Diabetes in the Tropics.—Sir RICHARD HAVELOCK CHARLES, K.C.V.O., Lieutenant-Colonel I.M.S., opened this discussion. It could scarcely be said that diabetes was a tropical disease, but it could be said that its peculiar prevalence amongst the Hindu races in India, and especially its very considerable increase in that country of late years, gain it sufficient interest to afford a practical subject of debate in the Tropical Section. In India, as in Europe, one defined diabetes as an intractable and constant glycosuria, associated with serious general symptoms and marked impairment of health. If the brunt of disease in cold climates fell on the respiratory system, in the tropics it was on the gastrointestinal canal that the burden was heaviest. Hence, malassimilation of food and its consequences was the root of many troubles. Regarding glycosuria as a symptom of malassimilation, its relationship to dyspepsia as a cause was easy to comprehend. There were cases of "simple glycosuria," supposed to be comparable to cases of "physiological or intermittent albuminuria; that is, they were called so when the practitioner could easily control them; but when control failed, then he called them diabetes mellitus. The typical diabetic case was easy of diagnosis, for in association with the glycosuria would be the cardinal signs of polyphagia, polydipsia, polyuria, and possibly emaciation. But every exception and variety existed; nothing but the lapse of time could enable us to say definitely as to the benign nature of a given case. We might surmise, but when it was borne in mind that glycosuria would entirely disappear for a long period and then recur, with possibly considerable malignancy, we must be guarded, as such periods of latency could not be justly estimated; and the very causes assigned for glycosuria were as commonly associated with the onset of diabetes mellitus, though we admitted that all who had glycosuria were not diabetics. Practically every case coming before the speaker had had symptoms of dyspepsia, and one might say: No diabetes without indigestion, its forerunner. What was there in lower Bengal to account for the commonness of the disease there? The lazy and indolent rich suffered; the overworked medical and legal practitioners were taxed with the scourge. What was there in common between these classes? Simply indigestion and its consequences. The menial element even afforded examples in Calcutta, though up-country, so far as the speaker knew, is was rare amongst this class. Why? Money was more plentiful, excesses more possible, life's conditions more irregular and strenuous—the result being digestive disturbances. The Marwari in Rajputana were but comparatively little attacked; in Calcutta they were very common victims. In that city they had high finance, and thus, working the machine to the utmost and attending least to its needs, received offended Nature's punishment for errors of diet and digestion. The Calcutta climate and hustle even overthrew the Chinaman, here furnishing the exception to his so-called immunity from diabetes. In the Punjab diabetes was a comparatively rare disease, whilst in Bengal it was exceedingly common and growing more so. For Bengal, the speaker said, he would divide the somewhat indefinite and unsatisfactory causes into remote and immediate. Amongst the forms were: (1) Depressing climate; (2) defective hygienic conditions, indolence, lack of exercise, overcrowding; (3) city strain *versus* bucolic ease—the disease was more common amongst old residents of Calcutta than inhabitants of the rural areas; (4) severe struggle for life under altered circumstances; (5) rich living, too great excess of carbohydrate food, special tendency to digestive troubles. Among the more immediate causes were: (1) Excessive venery; (2) mental or nervous strain, fright, bereavements—in fact, the overtaxing of the nervous system in the pursuit of knowledge, business, or pleasure was, one might say, the direct incentive to the onset of the disease, and then, if the essential cause—toxic agent or otherwise—were present, diabetes was the result. What struck one the most in India was the great preponderance which this disease bore to the Hindoo people, attacking them more than Musulmans, Beharis less than Bengalis. The Sonthal or Hill man rarely suffered, though Nepalese high officials furnished many cases. The Marwaris of Calcutta were more a prey to it than their brothers in Rajputana. In Bengal the Brahmins, Kyasths, Byades were more affected than the other castes. As in the West, it affected mostly those of the upper classes; but by no means always so, for very frequently cases from the menial orders were treated in hospital. The speaker did not think that any people in the plains of India were immune to this disease. Regarding sex, while it was true that males suffered mostly, still the speaker's experience had led him to form the opinion that the women of India were by no means as free from the disease as was formerly considered. Assurance companies in India should be on their guard in all cases of glycosuria. This was more especially for those taking chiefly Indian lives. Considerable experience in assurance work had taught him that companies had suffered losses through carelessness in accepting risks with a history of glycosuria.

Dr. RAI KOILAS CHUNDER BOSE, Bahadur, C.A.E., Calcutta, said that there was not the slightest shadow of a doubt that, with the progress of civilization, of high education, and of increased wealth and prosperity of the people under the British rule, the number of diabetes cases in India had enormously increased. Nearly 10 per cent. of the well-to-do class of Bengali gentlemen suffered from it. From close observation he had been induced to believe that the factors of diabetes lay in the liver, the gastrointestinal tract, and the nervous centers. It was difficult to state the part food played in the production of diabetes. True it was that the Indian's diet chiefly consisted of rice, flour, pulse, and cereals of diverse kinds; but so long as there did not exist the essential cause of diabetes, which was still unknown, they exerted little or no deleterious effects upon health, and a man might continue to take carbohydrates and sugar his life long and still not suffer from diabetes. He might suffer from temporary glycosuria. The speaker did not agree with those who believed that carbohydrates were the only factors of diabetes, for meat-eaters were not immune against the disease. In confirmed cases ants clustered round the limbs of a diabetic patient, and often caused breaches in the continuity of the surface of the skin. He had seen cases where patches of epidermis had been actually eaten up by ants. It was very difficult to say whether the disease was transmitted from one generation to another, or whether the succeeding generations, following the habits of their predecessors and living under the same environments, rendered themselves liable to the influence of diabetes. He had seen a regular group of diabetic patients in one family, and had also seen husband and wife suffering from the disease. Males were more susceptible to diabetes than females, and the proportion was about three to one. It was not always wise to attach any special value to high or low specific gravity of urine in determining the progress of the disease. Low specific gravity did not necessarily mean arrest of progress, nor did sudden disappearance of sugar from the urine indicate cure. In chronic cases the sudden disappearance of sugar foretold approaching complications of a serious nature. Sciatica was an obstinate complication of the Indian diabetes. When a

patient gave a history of bilateral sciatica he probably was the subject of diabetes. Indeed, the speaker never missed finding diabetes in patients who suffered from sciatica on both sides. The skin of a diabetic patient was always covered by patches of eczema. The prepuce was mostly affected by it. Phimosis was a common complication, and gave much trouble. The females suffered from prurigo. Carbuncle was a grave complication, and early interference was necessary to save the life of the patient. In some cases its appearance was preceded by a pause in the excretion of sugar. Gangrene was a fatal complication. Elderly people usually succumbed to it; young men might occasionally recover. A tight shoe or a puncture from a pin might give rise to it. We had no cure for diabetes. We simply palliated the symptoms and gave temporary relief to the patient. Aspirin and antipyrin reduced the micturition and relieved thirst and burning, but antipyrin should on no account be given when the kidneys were seriously affected. Jumbul reduced the specific gravity and the quantity of sugar; its prolonged use was followed by gastric troubles; it could never effect a cure. Codeine was gradually getting out of vogue and, in fact, did no good except in reducing the frequency of micturition. Milk was the best diet. Change of air seemed advisable; the Indian diabetics invariably did well in the hills of Darjeeling.

Dr. Rai Devendranath Roy of Bahadur said that the ancient Hindu physicians called diabetes mellitus *prameha* or *madhu meha* (sweet discharge), and diabetes insipidus *soma roga* (water disease). The causes were believed to be sexual excesses, grief, hard labor, mental worry, lassitude, indiscretion in diet, and dyspepsia. As symptoms they described a very large flow of urine, loss of eyesight, intolerance of heat, lassitude, inordinate thirst, a voracious appetite in some, loss of appetite in others, general loss of flesh and strength, premature senility. As complications they mentioned: (1) *Saráhiku*, circular inflammation, with raised edges and depressed center; (2) circumscribed inflammation resembling the back of a tortoise, accompanied by severe burning sensations; (3) *Jalini*, the inflamed surface was studded with small ulcerations and looked like an ordinary fishing net, and it was accompanied by severe burning sensation; (4) *Billüta*, affected part livid, very painful and ulcerated, usually on the abdomen or back; (5) *Alâji*, blackish or reddish eruption, very painful; (6) *Musurika*, very painful papules the shape and size of musur (a sort of lentil); (7) *Sarsapika*, a painful eruption the shape and size of a mustard seed; (8) *Putrini*, a large inflammatory area studded with minute pustular eruption; (9) *Bidárikâ*, inflammatory masses the shape and size of large tubes; (10) *Bidradhi*, inflammation, followed by accumulation of pus. In the treatment the patients should avoid night-keeping and exposure to heat. Long walks in the fresh air, riding, and physical exercises were advised. Sexual excesses should be avoided. The following articles of diet were recommended: New rice, curd, flesh of animals living in swamps, fish, sweets, wines, vinegar, excess of oils and onions. They should not drink milk, eat fish and meat at the same meal; sugar cane and preparations made from its juice should not be touched; excesses of acid and salt should be avoided. The following articles of diet were especially recommended as most beneficial: Barley, flour of old wheat, Moong dal, Arabar dal, Chena dal (Bengal grain), fried rice, sesame seeds, meat juice, old wines, old honey, whey, sparrows, pigeons, rabbits, snipe, peacock, venison. Of medicines they recommended jumbul, seeds and roots of lotus, dates, all bitters and astringents.

Dr. Sandwith, F.R.C.P., consulting physician to Kass el Ainy Hospital, Cairo, said that diabetes was one of the common diseases among Egyptians, who lived chiefly on bread and vegetables, instead of meat, and were very fond of sugar in all forms. The statistics of the Kass el Ainy Hospital showed only 65 admissions for diabetes during eleven years, the total number of medical cases having been 8,191. During ten years there were only four admissions for this disease in the Egyptian army hospitals, with the average strength of the army for these years at 18,160. As regards treatment, well-to-do patients should be warned not to travel during the acute stage, nor with any unnecessary fatigue, for he had seen three visitors, who had been recommended to winter in Egypt, die within a few days of their arrival there. The favorite remedy for diabetes among the Egyptians themselves was a pill made of ox bile and the seeds of a common indigenous plant, called in Arabic "helba," being the *Trigonella fœnum græcum* (fenugreek). He had tried this remedy upon patients for more than a month at a time, but without benefit.

Lieutenant-Colonel G. M. Giles, M.G., F.R.C.S., suggested that possibly diabetes within the tropics might be due to injury of the nervous system owing to exposure of the bare head to the sun. In India diabetes was essentially a Bengali malady. Now, the Bengali went about with a closely-cropped bare head, and in this respect he differed from every other Indian and almost from all other tropical men. Diabetes was also common among the upper classes in Egypt. Here again the well-to-do Egyptians, though they did not go bareheaded, wore only the very inadequate fez cap, which, though of good nonactinic color, protected only a small portion of the skull.

Professor Ziemann said that diabetes was extremely rare among the negroes of Lower Guinea. The negroes of West Africa did not protect their heads from the action of the sun.

Major G. T. Birdwood, T.M.S., mentioned the case of a friend who contracted diabetes shortly after his wife had contracted the disease, and subsequently his two children became affected. As regards life insurance, he thought any permanent trace of sugar in the urine should be regarded as most serious. He pointed out that the dieting of natives suffering from diabetes was extremely difficult. Their staple food was rice or wheat, and if we cut this off there was little to fall back upon.

Dr. H. Fernando, B.S.C., Senior Physician to the General Hospital of Ceylon, said diabetes was very common among the educated higher classes of natives of Ceylon. He did not consider dyspepsia an important cause. It was certainly common among the long-standing cases, but at the commencement the patients had good digestive powers. Colonel Giles's theory that the disease in the tropics might be due to insolation was not borne out by the experience in Ceylon. The Tamil coolies, who worked with their heads bare, did not suffer, as a rule, from diabetes.

Major A. H. Nott, T.M.S., considered the influence of dyspepsia as very doubtful in the causation of diabetes.

W. H. de Silva, M.B., F.R.C.S.E., Lecturer on Materia Medica in the Ceylon Medical College, Surgeon Victoria Eye Hospital, Colombo, said ocular symptoms were not in any way specific in nature, but were due largely to malnutrition and toxemia, or to an arteriosclerosis as the result of chronic diabetes. They disappeared under ordinary treatment, with the improvement of the glycosuric index. With regard to the dietetic treatment of diabetes, it was often felt in countries like Ceylon, where the staple food of the people was rice, that it was extremely difficult to get the patients to give up their ordinary starchy food entirely, and it was worth while investigating whether any of the cereals recommended by the older Indian medical writers, like Susruta and Charaka, were advisable.

Sir Patrick Manson, K.C.G.M., F.R.S., said diabetes was rare in China, although there the natives exposed themselves freely to the sun; many were overfed, many were overworked, and subjected themselves to all the usual accepted causes of diabetes. The interesting point of this Bengal diabetes was its endemicity. It was curious how history repeated itself. It might be that in the matter of the etiology of diabetes it was about to repeat itself again. Diseases formerly attributed to food, exposure, nervous

influences, heredity, and so forth, were now known to be germ diseases. Thus with leprosy, tuberculosis, and sleeping sickness. In his mind the endemic diabetes of Bengal suggested a germ disease.

Dr. Louis W. Sambon, lecturer to the London School of Tropical Medicine, agreed with Manson as to the germ nature of diabetes. He said the disease presented many features common to parasitic diseases. It had a peculiar distribution both geographically and topographically: it showed a marked tendency to increase or decrease in periods and places; it attacked animals as well as man; it affected the infant as well as the adult, though far more frequently the adult male, no doubt owing to greater exposure; it exhibited an undoubted tendency to occur in families, frequently passing from husband to wife and from parent to child. Indeed it had long been regarded as hereditary. The contagiousness of diabetes had already been suggested by Schmitz on account of the frequency of conjugal diabetes. Cases of conjugal diabetes had been recorded by most authors. Hofmeister mentioned no less than 200 cases. The disease was rare in children, but many cases had been now recorded in children under one year of age. True diabetes mellitus had been described in dogs by Friedberger, Fröhner, Schindelka, Eichorn, and others; in horses by Heim, Rueff, and Dieckerhoff; in monkeys by Leblanc. In comparison with its incidence in European countries diabetes was a rare disease in America. A very interesting fact, however, was that the disease was gradually increasing in the United States. It would be important to have accurate information as to the presence of true diabetes in China, Japan, Australia, and the Pacific, where until lately it was believed to be absent. His experience of diabetes in the south of Italy was contrary to the food theory. Diabetes mellitus, like pellagra, scurvy, gout, beriberi, was now attributed to faulty metabolism; he had no doubt that all these so-called food-diseases would soon take their place among the germ diseases.

Dr. P. J. Cammidge said he had no doubt that in at any rate the majority of cases of diabetes lesions of the pancreas, and particularly the islands of Langerhans, were responsible for the disease. This disease might arise either by extension from the duodenum or by way of the blood-vessels. With regard to disease of the blood-vessels the most common was arteriosclerosis. This arteriosclerosis was also responsible for the albuminuria which occurred in the later stages of some diabetics; it was not, as was commonly thought, the effect of the irritating action of the sugar on the kidneys.

Dr. W. Carnegie Brown, M.R.C.P., said that the belief that diabetes was rare in the Chinese race was erroneous. That error had been copied by one writer from another through several generations of textbooks. As a matter of fact there was no race predilection for diabetes, and it was very common among the upper classes of Chinese. With regard to what had been said about the possibility of diabetes being of parasitic origin, it was perhaps rash with our present experience to say that it could never fall into the voracious grasp of the parasitologist, but at present clinical experience would seem to indicate that if there was one disease which was purely and certainly an endogenous disorder of metabolism, the problems of which were to be solved by biochemistry alone, that was diabetes. Though our knowledge of the pancreatic ferments was still incomplete, the comprehension of the processes of intestinal digestion was now greater and clearer than it had ever been before and we knew enough about the interrelations of the secretions of the duodenal mucosa and the pancreas to justify the hope that the whole problem of sugar metabolism was not far from solution. In the tropics there were excellent opportunities for clinical determination of how far the absence of presecretion from the duodenum and secretion from the pancreatic juice might be remedied by the administration of trypsin or pancreatic or duodenal extract or substance. So far, we had in diabetes no means of determining whether the particular case was due to the duodenum failing to supply presecretion, or the pancreatic cells failing to respond to the stimulus of that substance, or even whether these ferments were normal, but the liver and muscular tissues were unable to deal with the sugar, so that the administration of pancreatic remedies must be to some extent haphazard; but it was significant that they had been highly successful. The speaker's own experience of pancreatic substance and of trypsin had been considerable, and it was altogether encouraging; the potential motility of this line of treatment seemed to be all the greater in that it enabled a patient to take during this administration a limited amount of carbohydrate food without aggravation of his symptoms. Irksome and disagreeable as the restriction of carbohydrates was to a European, it was to an oriental far more severe, and often altogether intolerable. The sudden arrest of his staple and invariable form of nourishment was not infrequently followed by dangerous nausea and depression. As a matter of fact, rice was less hurtful to a diabetic than other forms of farinaceous food, and small quantities should be allowed. Combined with pancreatic treatment, a considerable amount was readily tolerated. Sugar in any form was impossible, even in a greater degree than in temperate climates, and its ingestion was invariably followed by polyuria and consequent exhaustion. In the tropics opium was preferable to codeine, though neither seemed to be of much use. The systematic administration of narcotics in diabetes was as unsuccessful as it was unscientific.

Dr. T. M. Mallick said carbohydrate given to a diabetic patient brought out more sugar in the urine than that introduced as food—sometimes twice or thrice as much. This, he thought, was due to the breakdown of the tissues caused by sugar circulating in the blood and acting as a toxin. That this was the result of breakdown of the tissue was supported by the fact that there was an increase in urea as well as in the total acidity of the urine. If carbohydrates were withheld early in the onset of the disease, sugar in the urine disappeared, and very often the power of carbohydrate assimilation was restored after some time. Urea eliminated by Indians was very much less than that stated in European books—very often half of that quantity. This was due to their food being poorer in nitrogenous material, and to their deficient musculature, as well as to their comparatively less active life. In diabetes this invariably increased along with the acidity of the urine. Diabetes was very common among the educated Hindus in Lower Bengal because (1) being vegetarians they did not get sufficient amount of proteid element in their food, especially in the building period of life (early life). This caused their growth to be defective, especially their muscles. Bengalis were notoriously poor in musculature. (2) Their staple food was rice, which contained the largest amount of starch (95 per cent.) and only 5 per cent. proteid. Starch with a poor association of proteid was always less assimilable than when the proteid associate was more. The same quantity of starch brought out more sugar in the urine when given as rice than when given as wheat. (3) The educated Bengali, as a rule, greatly neglected physical exercise. Thus there was a very large intake of carbohydrate of the least assimilable sort, and little output of it by muscular exercise, causing a large excess of sugar in the blood which very naturally flowed out through the urine. (4) Mental strain or worry in life. Being married early in life, they were already saddled with a family before they had finished their education period and commenced earning for themselves. This caused a severe strain in their early professional life, and they broke down under it. There was nothing like mental worry to distort metabolism and assimilation.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Connection with the Seventh Triennial Congress of American Physicians and Surgeons.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 503.*)

DR. A. W. DE ROALDES OF NEW ORLEANS, LA., PRESIDENT.

Thursday, May 9—Third Day.

The Problem of Asepsis in the Routine Office Work of the Laryngologist.—DR. THOMAS HUBBARD of Toledo, O., read this paper. He made a plea for the same aseptic precautions in office work as in major surgery and believed that in future more of the minor work now done in the office would be transferred to special hospitals. Most of the office work was now done under conditions which did not measure up to the requirements of modern aseptic and antiseptic surgery. All operators had experienced anxiety over cases having symptoms of sepsis and cases of delayed healing arose which could not be accounted for by defective operation. He then presented detailed features of office routine which he considered essential, dwelling on disinfection of instruments, sterile solutions, napkins, care of instruments to prevent rusting, etc., sterilization of the area to be operated on, avoidance of too firm packing, quality of air used in atomizers and air tanks, etc. A little trouble taken in all these respects would remove practically all the possibly injurious factors which existed in the routine work of the office as ordinarily carried on. The surgeon, in whatever special field or working environment, must bear in mind that only by high ideals in the refinement of cleanliness in both theory and practice could he expect to stimulate his assistants and associates to the proper discharge of their part of the work. The aim of every operator should be to develop a thoroughly consistent system of approximate surgical cleanliness.

DR. GORDON KING presented a device for sterilizing sprays in office practice. He had been very much interested in Dr. Hubbard's statements in regard to the sterilization of instruments and of the air. Filters placed over the ends of sprays showed conclusively that as ordinarily used the spray must project many microorganisms over the operative field. Dental napkins were of much service in office work, but paper napkins could be used instead, and they were practically sterile.

DR. W. F. CHAPPELL of New York spoke of the danger of infecting the doctor from the sputa of patients. He himself had had a septic dermatitis of the face, eyes, and neck during the past winter from the expectoration into his face by a patient of pus from an old pharyngeal abscess.

DR. GEORGE L. RICHARDS suggested the use in such cases of ordinary automobile goggles which could be made to hold a gauze mask.

DR. R. C. MYLES was accustomed to cover his patient and himself with a special kind of oiled silk. He frequently had a nurse hold a pane of glass before his face during operations. Such a device was more convenient than a glass shield suspended from the ceiling. Instruments must be boiled frequently. Asbestos-packed syringes were the only ones meeting all requirements. It was true that we had no definite knowledge of the occurrence of much sepsis in office practice, but it was possible that there were some forms of septic conditions not localized in their manifestations.

A Review of the Methods in Use for the Removal of Adenoids, with a Description of a Method which is Thorough, Rapid, and Safe.—DR. GEORGE L RICHARDS of Fall River, Mass., exhibited a large collection of various instruments. He thought that undue stress had been laid on the necessity of cleaning out the fossa of Rosenmueller on account of its effect on the ear. His own preference was for the adenotome of Schuetz, which had been presented to the Association some years ago by Dr. Farlow It found its best employment in young adults without anesthesia. The operator should have three sizes, as there were but few pharynges in which one size or the other would not answer every requirement. In cases of young children under anesthesia, and held in the arms of the nurse, a palate hook should be used, so as to gain a good idea of the size and exact location of the mass to be removed. A little side dissection of the growth with the finger toward the center aided in getting it within the fenestrum. The instrument was then pushed firmly back against the nasopharynx, and as the knife cut through the growth came out in one piece. Instruments of different sizes might be used in the same case if necessary to remove small fragments left after the main cut. The adenotome was a slender instrument and the knife might occasionally break. The instrument should be carefully examined before each operation and care also was required in taking it apart and putting it together again.

DR. JOHN W. FARLOW recalled a previous meeting of the Association, at which he had presented the adenotome advocated by Dr. Richards. The disadvantage of the instrument was that we could not well see into the nasopharynx and determine just how large an instrument should be used. Hence he did not prefer the adenotome for very young children. In proper cases, however, the guillotine seemed to him to be the ideal instrument.

DR. D. BRYSON DELAVAN said that his experience with this particular instrument had not been fortunate, as he had had one break, leaving a portion of the metal in an adenoid mass. Fortunately it was removed without untoward incident. One objection was that the pharynx had to fit the instrument, whereas the latter should fit the pharynx. His own preference was for the Frothingham modification of the Gottstein knife. Hard rubber palate retractors were preferable to those of metal. He believed that it was absolutely necessary thoroughly to clear out the fossa of Rosenmueller in order to obtain relief from ear symptoms.

DR. W. K. SIMPSON of New York was also an advocate of the Frothingham curette. The Concannon forceps he thought to be the best model of this class of instrument. It had a guard which enabled the adenoid to be removed in one mass.

DR. L. A. COFFIN believed that the success of any instrument depended largely on the "man behind the gun" and his experience. There were very many poor models on the market of good instruments which had been changed by the makers from the original models.

DR. HENRY L. SWAIN was also a partisan of the adenotome. If, however, we had in the nasopharynx a central mass on two sides, we were liable to miss with this instrument the side strings from the main masses. The adenotome ought to be followed up with a blade-curette.

DR. W. E. CASSELBERRY had used the adenotome for a long time, but was not satisfied with it. There was a liability to leave small pieces of tissue behind the posterior nasal openings. Some sort of supplemental operation was therefore necessary. This was a limitation of the efficiency of every adenotome he had ever seen. The adenotome would answer if used with the curette.

DR. G. A. LELAND said that unless the fossa of Rosenmueller was cleared out, there would be recurrent earache. Smaller instruments than generally used would suffice for the purpose of cleaning out the fossa.

DR. R. C. MYLES said that the finger ought always to be introduced into the nasopharynx in order to guide the intelligent application of any cutting instrument. The axis of the instrument should be kept in line with the axis of the head. Unless this was done, parts would be damaged. The fossa of Rosenmueller ought always to be cleaned out.

Dr. G. Hudson-Makuen exhibited a modified Gottstein instrument which he had found of great service.

Straightening the Nasal Septum.—Dr. A. W. Watson of Philadelphia discussed this question, with special reference to the operation devised by him several years ago. It was his view that when a septum could be put in proper place without resection the patient was better off than if the septal framework had been removed. The methods of his operation for which he claimed originality were the overlap and the beveled incision. This procedure was applicable to the vast majority of cases. In every case the two conditions to be met and overcome were resiliency and redundancy of tissue. The author thus described his operation: Incision on convex side of septum from behind forward just beneath the angle of deflection, following the angle to its anterior extremity and then curving upward for a short distance. This cut should be beveled and by preference was *not* carried through the mucosa of the concave side. The upper part of the septum was then pushed over the lower portion into the opposite side, thus overlapping the lower portion. If the angle was perpendicular the incision was then made behind the angle, the bevel being from behind forward. An incision was also made at the base forward from the first incision, forming a triangular flap. The posterior edge of the anterior portion was then pushed over the posterior portion. If, as was frequent, both horizontal and perpendicular angles existed, both incisions were made meeting at the base. The anterior fragment was first made to overlap the posterior and then the upper portion, including the anterior portion, was made to overlap the basal portion. This formed a double locking. If the deflection extended into the bony septum the bony deflection was easily broken and replaced with forceps. If the septum thickened below the horizontal angle the thickened base which protruded into the formerly obstructed naris should be dealt with as were spurs, etc. If the septum was thin in the lower part and projected unduly into the naris, it might be broken into a perpendicular position in line with the upper portion, thus increasing the overlap and making the septum more firm, the bony base uniting by bony union. The author passed into the formerly obstructed side a folded piece of antiseptic gauze long enough to extend the length of the former deflection and about one-third to half an inch wide, thick enough to pass easily. This should be changed every three or four days until healing was complete, about four weeks. The instruments used were a straight knife like a tenotome and the same with a blade at an obtuse angle. These sufficed for the horizontal incision. For the perpendicular incision he used a knife with a small blade bent on the flat almost to a right angle and sharp on both edges. The forceps was a modified Adams, the fenestra being lengthened to an inch and a quarter, so as to reach any part of the bony septum.

Dr. A. A. Bliss of Philadelphia had had much satisfaction with the Watson operation. Submucous resection was being overdone. For the angular deflections the Watson operation was preferable.

Dr. Emil Mayer would also commend the Watson operation for angular deflections. He would like to lay stress on the matter of freshening the edges of the floor on the concave side, after having performed the operation on the convex side. This gave a double opportunity for holding the part pushed over into the concavity. He preferred rubber tubing to gauze for packing. No one operation sufficed for every case.

Dr. W. E. Casselberry asked if it was not possible to obviate the second operation sometimes called for, namely, the removal (as he would take off a spur) of the thickening along the long part of the horizontal cut protruding into the naris of the convex side after healing. The Watson operation could be done quickly, efficiently, and without difficulty. He preferred to operate under general anesthesia.

Dr. Watson stated that by preference he went through the mucosa of one side only, but this restriction was not always possible.

Dr. W. L. Ballenger of Chicago thought that if we could save the framework of the septum it was most advisable so to do. He had had one sinking in of the nose after a submucous operation, not having made due allowance for the chondritis undoubtedly following the injury.

Dr. R. C. Myles referred to the various operations devised during the last few years. Submucous operations were not free from danger, as he knew of two cases resulting fatally. The deeper the operation on the bony septum the greater the element of danger. He thought the perpendicular plate of the ethmoid a very difficult thing to handle.

Dr. J. Solis-Cohen made comparisons between the mechanical principles involved in the Watson and in the Gleason operations. He had seen serious cerebral effects follow the latter.

Large Tumor of the Laryngopharynx removed by Subhyoid Pharyngotomy.—Dr. W. F. Chappell of New York City reported this case. (See page 55.)

A Plea for Local Anesthesia in Operations on the Maxillary Sinus.—Dr. Gordon King of New Orleans read a paper with this title. He took the position that we ought to minimize the dangers of anesthetics as much as possible and that we ought consequently to employ local instead of general anesthesia whenever and wherever possible. In operations around the mouth and pharynx general anesthesia caused annoyance and delay from nausea and vomiting, inhalation of blood and secretions into the larynx and frequent interference with the administration of the anesthetic. The author was led to employ local anesthesia in antrum operations two years ago and had used them since that time. He was a loyal adherent of the Caldwell-Luc operation and had been able to finish it in less than twenty minutes. He swabbed the mucosa briskly with a 10 per cent. cocaine solution and when the area had become insensible to the needle point he injected a solution of 2 per cent. strength with 1-2.000 adrenalin along the line of incision, at first superficially into the submucous tissue and later into or under the periosteum. This done, incision was made down to the bone and the periosteum elevated until the exact situation of the infraorbital foramen could be made out, when to insure perfect and widespread anesthesia a few drops of the solution were injected into or around the trunk of the infraorbital nerve at its point of exit. He found it prudent not to lay bare the nerve itself, as this might lead to postoperative neuralgia or neuritis. The bone being sufficiently exposed to allow of easy access to the antral cavity, the latter was opened with a chisel or electric burr, when several drops of 10 per cent. cocaine and some adrenalin solution are introduced into the cavity, which was then swabbed by means of a cotton carrier. A few minutes must be allowed at this point for absorption of the solution, and the time might be utilized by applying a pledget of cotton saturated with the solution under the inferior turbinate, where the counter opening was to be made into the nose. The antrum was then curetted, the counter opening made and the buccal wound sutured. Adrenalin lessened the blood flow and prolonged the effect of the cocaine, while offsetting the toxic tendency of the latter. The author had followed the foregoing plan in some fifteen cases and with most satisfactory results. In two instances he had performed the radical operation on the frontal sinus under local anesthesia, but here the results had not been so satisfactory, as this region was more sensitive and less susceptible to thorough cocainization.

Dr. R. C. Myles stated that he had operated on two hundred antral cases during the last fifteen or twenty years, but that during the last eight or ten years not more than 2 per cent of the operations were done under general anesthesia. He had gradually diminished the strength of

the cocaine solution until now he rarely used more than one-eighth per cent. The operation was practically painless, unless we got near some dental nerve. Water, by its pressure on the nerves, sometimes gave as good anesthesia as did cocaine. Of late years he had preferred the nasal route, introducing a light platinum needle under the inferior turbinate and then introducing the cocaine and adrenalin through the opening thus made, for the most of the pain was in the antral mucosa. He did not believe in putting the cocaine on a region on which he did not intend to operate, and therefore considered it unwise to spray it into the nose. He knew of several deaths from general anesthesia. They were more common than published reports would lead us to believe.

Dr. W. E. Casselberry could also commend the use of local anesthesia for these operations. He had not been able, however, to operate as quickly as had Dr. King. The injection of some of the solution into the region of the infraorbital nerve, as had been suggested by Dr. King, would doubtless be a very useful addition to the procedure.

Dr. King, in closing the discussion, said that local anesthesia facilitated the operation. It obviated all the objections which arise from the use of a general anesthetic in operations about the mouth. After an opening was made into the antrum, a 10 per cent. solution could be injected, and by the time the antrum was thoroughly opened it was pretty insensitive to pain. A still stronger solution could be swabbed on the interior surface of the cavity.

Myxofibroma of the Nasopharynx.—Dr. D. Braden Kyle presented a specimen removed from a man of twenty-four years, who complained of inability to breathe and of almost continuous pain or aching in the region of the frontal sinus or over the bridge of the nose. On the right side a mass almost protruded from the naris. The mirror outlined a mass in the nasopharynx, but it did not extend below the margin of the soft palate. There was considerable catarrhal discharge, but no evidences of sinus or ear trouble. A distinct swelling was evident at the inner corner of the right eye. The left naris was occluded, owing to pressure of the tumor on the septum. The mass was removed without difficulty and six weeks later the patient was in good condition, with both nares of practically the same size. The interesting points in the case were the site of origin, at the posterior end of and under the superior turbinate, the symptoms of nasal occlusion by septal pressure, the fact that the growth did not follow the path of least resistance, the practical absence of hemorrhage, the pedunculated nature of the mass removed, the absence of ear and sinus involvement. The bony septum seemed to have been softened by the pressure and inflammatory process. It was easily forced back into the median line by the nasal dilator and remained in position without the aid of splints.

Dr. John W. Farlow stated that one symptom in a patient of his, not present in that of Dr. Kyle, was a change in the voice. The growth was larger even than in Dr. Kyle's case. The character of the voice changed immediately after the tumor was removed. His patient had formerly pronounced the letter "m" as "p," but as soon as the growth was removed the "m" came out very clearly.

Dr. A. W. Watson had had a similar case in which the circumference of the growth was about six inches. It had involved both sides of the septum and extended into one antrum, producing some facial protrusion on that side. The large mass filling the nasopharynx was removed with the snare. The entire vault of the pharynx was covered, however, with similar material, which was reproduced as fast as it was cleared away, but under the influence of electric needles it began to diminish and finally ceased growing.

Dr. Gordon King had recently removed a myxofibroma as large as a hen's egg and found the site of attachment to be the ala of the nose.

Dr. William Lincoln of Cleveland said that not all cases were so favorable as was that of Dr. Kyle in regard to distribution of the blood-vessels. In a recent case of his own, snares and forceps were useless and he was obliged to remove the nose on one side, lay it over on the face and so gain free access to the tumor. Adhesions were separated with the spatula and the cautery used. In removing the nose he had cut in on the sound side so that the inevitable suppuration was discharged, not through the wound, but into the pharynx. The mass projected into the nasopharynx and needles were used here, as explained by Dr. Watson.

Dr. J. N. Mackenzie gave the history of a case illustrating the occasional impossibility of removing these tumors through the internal passages. They might become rooted in many places. In one instance he had been compelled to turn the patient over to the general surgeon, who did a modified Langenbeck operation, dissecting out the growth in that way. Severe hemorrhage accompanied the procedure.

Dr. W. E. Casselberry said that the tumor mentioned by the last speaker was probably a fibroma, while Dr. Kyle had spoken of myxofibroma, which was quite another form of neoplasm. The two conditions should not be confused, because the treatment of one was entirely different from that of the other.

Dr. Kyle, in closing the discussion, said that it was difficult to see why such soft growths should cause so much bony displacement.

Epithelioma of the Tongue; Early Diagnosis; Operation; Recovery.—Dr. Robert C. Myles of New York reported the history of a patient, a man of sixty-four years, who had been annoyed for a few weeks before coming under observation by a sensitive spot on the left side of the tongue, a little in front of the insertion of the palatoglossus muscle. At this site there was a small, hard, and roughened area, suggesting malignancy. Iodides were tried without avail and operation was decided on. This was done by Dr. J. A. Bodine, who thoroughly dissected out all the superficial and deep cervical glands and also the submaxillary, salivary, and sublingual glands and much of the connective tissue along the jugular vein and carotid artery, in order that many of the small undetectable lymphatics might be removed. Then with heavy scissors section was made of the affected area in healthy tissue at a distance of from one-half to three-quarters of an inch from the margin of the growth. It was necessary to sever the left palatoglossus muscle and parts of the geniohyoglossus, styloglossus, hyoglossus, and lingualis. This caused the tongue to curl upward at the tip and to fall back on the epiglottis at the left base. The patient made a good recovery from the operation, which was done six months ago. The microscopist reported that the growth removed was a squamous-celled carcinoma. The glands removed were somewhat inflamed, but showed no metastases.

Dr. J. H. Bryan of Washington was very much interested in the subject of cancer of the tongue and related the histories of two personal cases under his recent care. The fate of the patient depended on the early recognition of the disease. The cases should be recognized in the precancerous stage. Recurrence sometimes took place on the side opposite to that of the original disease because of the richness of the tongue in lymphatics, the circulation of which the raphé was not able to shut off. The glands ought to be excised on both sides.

Dr. J. N. Mackenzie said that the Baltimore surgeons believed that the whole floor of the mouth ought to be excised.

Dr. George E. Shambaugh of Chicago said that he had had a recent case of cancer of the neck, which seemed to him to be rather unusual. He thought that the development of the tongue explained it. The anterior part of the tongue developed in halves, while the back part developed as a central piece.

A Prize Fund.—At the closing executive session it

was announced that the retiring President, Dr. de Roaldes, had offered the Association $500 for the establishment of a Prize Fund. This offer was gratefully accepted and it was voted to attach to the fund the name of the donor.

New Members.—The following were elected to membership: Honorary Fellows. Professor Leopold von Schroetter of Vienna. Active Fellows: Dr. Joseph S. Gibb, Philadelphia, Pa.; Dr. Christian R. Holmes, Cincinnati, O.; Dr. Chevalier Jackson, Pittsburg, Pa.; and Dr. George E. Shambaugh, Chicago, Ill.

Officers.—The election of officers for the coming year resulted as follows: *President*, Dr. Herbert S. Birkett, Montreal; *First Vice-President*, Dr. J. Payson Clark, Boston, Mass.; *Second Vice-President*, Dr. J. Edwin Rhodes, Chicago, Ill.; *Secretary and Treasurer*, Dr. James E. Newcomb, 118 West Sixty-ninth street, New York City; *Librarian*, Dr. Joseph H. Bryan, Washington, D. C.; *Member of Council* (to serve four years), Dr. A. W. de Roaldes, New Orleans, La. The determination of date and place for the next Congress was left to the Council.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS.

Held at the Academy of Medicine, New York City, September 9 to 14, 1907.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 497.*)

DR. EDWARD L. KEYES OF NEW YORK, VICE-PRESIDENT, IN THE CHAIR.

Leprosy; Proposals for Diminishing the Diffusion of the Disease.—Prof. R. CAMPANA of Rome, Italy, in this paper, said that considerations regarding the nature and special symptoms of leprosy led to the conclusion that a mutual understanding should be arrived at amongst civilized nations concerning the treatment of this disease and its aspects as an evil which affected the individual and society. Local treatment was necessary in leprosy in the initial stages of macular and tubercular symptoms. These could be arrested by radical surgical treatment, followed by cauterization. The most rigorous aseptic and antiseptic treatment of the ever-varying lesions was indispensable, according to the manner in which they developed in the patients, and this was especially the case in the latter stages of the disease. Tubercular leprosy was a purely local disease of much gravity, and its contagiousness, which had been proved experimentally, was in direct proportion to the shortness of the time that the malady had lasted. Hence the radical treatment of the disease was to destroy its manifestations as soon as they appeared. The severe mutilations and the grave febrile and phthisical phenomena which might occur in leprosy were the consequences of septic conditions caused by ulceration and trophic changes. Hence the treatment of patients in whom these lesions had occurred ought to be directed towards diminishing the injurious effects of these trophic changes, more particularly those of the joints, to prevent breaches of surface, and to arrest the continuance of sources of sepsis in the individual patients and in their houses and in leper asylums. When the phenomena of sepsis had occurred, the suitable treatment was to attack them courageously, studying when possible the special nature of the various sources of sepsis, and in abating them to bear in mind the unusual condition of the patients in whom they had developed.

Dr. DOUGLASS W. MONTGOMERY of San Francisco said it was frequently difficult to establish the source of the infection of leprosy, and so far as the first evidences of the disease were concerned, the physician rarely saw them. The early symptoms were such that the patient himself did not usually attach much importance to them, and it was only later, when the disease was well established, that medical advice was sought. A long time frequently elapsed between the initial symptoms and a well-marked case of lepra.

Dr. H. E. MENAGE of New Orleans recalled cases that had apparently originated from late lesions of tubercular leprosy.

Dr. WALTER REMSEN BRINCKERHOFF, U. S. Laboratory, Honolulu, said the question of the diffusion of leprosy was a public health problem of great interest. In Hawaii the disease had been kept under control for over forty years by means of segregation, and in watching the methods by which this had been brought about, he had been struck by the extreme difficulty that had been encountered in persuading lepers to go into segregation. The popular conception was that when a patient once entered a leprosarium it was to die, and this prejudice against these institutions should be overcome.

Prof. CAMPANA, in reply to a question, said the bacilli were found in the early lesions of leprosy, but not after the disease had attained its full bloom. The infectious character of the disease was most marked in its early stages; its virulence gradually diminished and finally disappeared entirely.

Dr. ISADORE DYER of New Orleans believed it was the experience of everyone who lived in a leper center that the bacilli of leprosy became attenuated with the attenuation of the types of the disease. In other words, that the trophic types were evidence of the fact that the disease was more or less effete. The disease spread gradually, and while it could not be traced from individual to individual, it spread numerically wherever it had been introduced. The method of isolation practised in Louisiana had not only reduced the number of cases from year to year, but had reduced it to nearly one-quarter what it was when isolation was commenced. He and his associates had come to regard the treatment of leprosy as practically the same as that of tuberculosis. The patient received plenty of fresh air and sunshine, with two or three baths daily, as warm as could be borne. In addition to this, they had followed the traditional treatment of leprosy, depending mainly on chaulmoogra oil, but in cases where that could not be tolerated in large doses, cod liver oil or some other oil was substituted with practically equally good results. Under this general method of treatment, after two or three years, some good results were achieved, and some evidences of the disease were removed.

Dr. PRINCE A. MORROW of New York City said the views expressed by Prof. Campana were certainly somewhat startling. Personally, he thought it was impossible to say whether the bacilli which escaped from the lesions of advanced tubercular leprosy were dead or alive. There was absolutely no culture method which could be relied upon, nor was there any experimental method. It would be a practical impossibility to isolate cases of leprosy only during the early stages of the disease, simply because in a large proportion of the cases the disease remained undetected in those stages. It was a matter of general knowledge that leprosy might exist for five, ten, fifteen, twenty, and even thirty years, with positive evidences of disease of the skin in the shape of macules and certain nerve lesions, and still remain unrecognized by the physician without a very thorough examination.

Dr. H. RADCLIFFE-CROCKER of London, England, said that leprosy was by no means a hopeless disease, and in the milder nerve forms the prognosis was fairly good. At all events, the duration of the disease was so long and the symptoms so trifling that they scarcely incommoded the patient.

Dr. BURNSIDE FOSTER of St. Paul said that his experience with leprosy among the Scandinavians had led him to recognize the communicability of the disease, but he believed that it was communicated with great difficulty, that

it could be engrafted only upon a peculiar soil, and that there were many who could not be inoculated with it.

Prof. Campana, in closing the discussion, said he did not wish to have it understood that he was opposed to isolating cases of leprosy, because it was difficult to state the exact time when the infective period of the disease disappeared. He simply wished to insist on the scientific accuracy of the observation that the infectious character of leprosy disappeared with the full development of the disease, and that in order to prevent the spread of the disease it was necessary to destroy the sources of infection. Nothing was said against the advisability of protecting the community against the spread of leprosy by proper segregation.

The Treatment of Leproma by Perforation and Cauterization.—By Dr. José Vineta-Bellaserra of Barcelona, Spain. The author stated that lepers were subject to febrile attacks of varying severity and duration. These attacks were already pointed out by the physicians of the middle ages. The fever frequently was so slight that the patient paid no attention to it. The attacks were brief, transitory, ephemeral and intermittent, and many patients mistook them for attacks of malarial fever, while others attributed the fever to a cold. They usually appeared in the evening or afternoon. In other cases there were severe chills, with a considerable rise of temperature. The chills and fever might be severe enough to suggest that of acute pneumonia, smallpox, etc. Frequently, a sudden and severe chill made its appearance, accompanied by an infection or digestive disturbances which threatened the patient's life, the attack coinciding with the infiltration and suppuration of the leprous tubercles. Sometimes they coincided with the invasion of the bullous eruption (pemphigus leprosus) or the lymphangitis and the edema which might occur during the course of the disease. When these symptoms were demonstrated, the speaker said he took the fine point of the galvano-cautery and proceeded at once to perforation and thermic cauterization of all the tissues invaded by the germ of leprosy. Immediately after the performance of this operation, a rather considerable quantity of pus was apt to escape. After cleansing the affected regions, the lymphangitis subsided, as well as the general symptoms, *i.e.* fever, intestinal troubles, nervous disturbances, etc. As regarded the general condition of the patients, they were built up by good food and tonics, especially the sulphate of quinine. Chaulmoogra oil was administered in large doses, and benzo-naphthol was given for the disinfection of the digestive canal. The speaker said he had tried the same procedure for the destruction of tubercular masses, especially on the face, with equally brilliant results.

The Treatment of Leprosy and of the Microbic Dermatoses with the Products of the Brazilian Flora.—Prof. Egas Moniz Barreto de Aragao of Bahia, Brazil, presented this paper.

Treatment of Lupus Vulgaris with Béraneck's Tuberculin.—By Dr. A. Lassueur of Lausanne, Switzerland.

Cutaneous Tuberculosis in the City of Mexico.—By Dr. Jesus Gonzalez Urena of the City of Mexico. The author stated that among 5,268 skin patients treated in the "Consultorio Central de Beneficiencia Publica" in Mexico from February 9, 1905, to August 20, 1907, there were 42 cases of cutaneous tuberculosis, distributed in the following manner: Tuberculous gummata, 19; lupus erythematosus, 11; lupus tuberculosis planus, 7; tuberculous ulcerations, 3; lupus pernio, 2; tuberculosis verrucosa, 2; tuberculous adenitis, 2. This gave an average of 8.73 per thousand of cases of skin tuberculosis for the total number of skin patients observed during this period. It was a noteworthy fact that in Mexico, a city situated at an altitude of 2,222 meters (7,221 ft.) above sea level, with a sky almost always blue and a very bright sun, lupus erythematosus was far more common than lupus vulgaris. It should likewise be noted that the ulcerative, gnawing, destructive forms of the latter were practically unknown there. The seven cases that came under observation all belonged to the flattened variety (lupus planus).

Contributions on the Nature and Treatment of Lupus Erythematosus.—Prof. Campana and Dr. G. Lanzi of Rome, Italy, presented a paper on this subject in which they made the following statements: 1. That lupus erythematosus often became an incurable disease under the treatment at present generally used. 2. That there were cases of lupus erythematosus upon which tuberculin acted in the same way as it acted on true lupus. 3. That there were some cases not cured under the most active surgical treatment, but which were afterwards cured with surprising ease by the use of mercury ointment, which had been recommended by Hebra as most efficacious, although not proving so in practice in many instances. One must be guided by an analysis of the conditions in order to distinguish the special peculiarities forming the basis of the disease in each case. To begin with an injection of tuberculin and get no local or general reaction would certainly assign the case to a basis quite other than the tuberculoid predisposition accepted by many, but not admitted by all in lupus erythematodes. To begin with local and general treatment with mercury and obtain no apparent improvement therefrom would not predispose one to continue that method of treatment. In cases where the mercury had failed, and the tuberculin had given a positive reaction, local surgical treatment was possible; where the contrary happened, and the physician in charge had not attempted precautionary tests, local treatment was injurious and even disastrous. A third remedy had recently been mentioned by many English and American specialists, namely, small, continued doses of sulphate of quinine.

Dr. Milton B. Hartzell of Philadelphia confessed to a certain degree of surprise at the large proportion of cases of lupus erythematosus in which Prof. Campana was able to obtain a reaction after the injections of tuberculin. Certainly that was not in accord with the experience of a vast number of dermatologists in the treatment of this disease. There were a certain number of cases of lupus erythematosus in which it was difficult to make the differential diagnosis between that affection and lupus vulgaris, and it was quite possible that a large proportion of the cases in which the reaction was obtained were in fact lupus vulgaris rather than lupus erythematosus.

Dr. Stafford Taylor of Liverpool, England, said the remedy in the treatment of lupus erythematosus which had proved most successful in his hands was pyrogallic acid. In the common or stationary types of the disease he used a ten per cent. ointment of pyrogallic acid in the same way as he used it in lupus vulgaris.

Dr. Samuel Sherwell of Brooklyn said that in cases where the mucous membranes were not involved, he had almost invariably obtained excellent results by the use of the curette, followed by the application of the acid nitrate of mercury.

Dr. Herman Lawrence of Melbourne, Australia, spoke in favor of scarification, followed by rubbing in iodoform, and then the application of a waxed India rubber pad under moderate pressure.

The discussion was continued by Drs. Joseph Grindon of St. Louis and Jay F. Schamberg of Philadelphia, and was closed by Prof. Campana.

Recent Researches on the Subject if Papulo-Vesicular Eczema.—By Dr. L. Brocq and Dr. G. Ayrignac of Paris, France.

Rosacea: Historical, Clinical, Therapeutical.—Dr. P. G. Unna of Hamburg, Germany, sent a communication on this subject, which was read by title.

Complimentary Deviation in Gonorrhea and Skin Diseases.—Drs. R. M. Miller and M. Oppenheim of Vienna, Austria, in this communication said that the serum of patients having gonorrhea invariably contained circulating substances which might be demonstrated by means of

the method of complementary deviation. These were first demonstrated by the authors in the serum of a patient who had died from gonorrheal arthritis. This original demonstration of antibodies which were produced by the gonococcus was confirmed by Bruck and later by Vannod. These antibodies were likewise demonstrable in gonorrheal epididymitis, prostatitis, metritis, and endometritis of a gonorrheal character, but their presence was not constant. The serum of certain individuals had in itself an inhibiting influence upon the hemolysis. The vast majority of these sera were derived from cases of psoriasis.

Methodical Scraping (Scratching) as a Diagnostic Method in Certain Dermatoses.—Dr. L. Brocq of Paris, France.

On the Value of an Absolutely Vegetarian Diet in Psoriasis.—Dr. L. Duncan Bulkley of New York read a paper on this subject, in which he offered the following conclusions: 1. The cause of psoriasis was as yet unknown. Many facts pointed to its not being a purely local disease of the skin, although the character of the individual lesions strongly suggested a parasitic element in their production; possibly one of the ordinary microorganisms, universally present, took on a pathogenic action when the soil was suitable. 2. Psoriatic patients often appeared to be in perfect health, but metabolic disturbances could generally be discovered by complete quantitative uranalysis. 3. The error was generally along the line of faulty nitrogenous metabolism and diminished excretion of the purin products. 4. Long observation of cases showed a decided increase of eruption with excessive meat eating. 5. Marked improvement in the eruption occurred under the same treatment when a strictly vegetarian diet was faithfully carried out. 6. Continued strict vegetarian diet was often attended with freedom from eruption, and relapses were often directly traceable to dietary errors in this direction.

Dr. H. Radcliffe-Crocker of London, England, said that in cases of psoriasis occurring after middle life in patients with an undoubted gouty tendency, the proper restriction of the nitrogenous diet was certainly indicated, but when we came to include cases of all ages, then he would have to take issue with the reader of the paper. The speaker said he had seen psoriasis in vegetarians and in butchers, and he had come to the conclusion that diet had very little influence upon the course of the disease. He believed, however, that anything approaching an excessive use of alcohol had an aggravating effect on the eruption. His conclusions in regard to the influence of diet upon psoriasis were totally unlike those of Dr. Bulkley. He recalled the case of a girl of thirteen, the daughter of a medical man, with well marked psoriasis, whose father had assured him that she was a natural vegetarian, and that she had never eaten a piece of meat of any size in her life. A study of the age at which psoriasis made its appearance would show that fully two-thirds of the cases had their onset before the age of thirty; that is, during a stage of life when errors in metabolism were comparatively few.

Dr. Veiel of Cannstatt, Württemberg, said that his results with the dietary treatment of psoriasis had not been as satisfactory as those of Dr. Bulkley, which was perhaps due to the fact that the gouty diathesis was not as common in Southern Europe as it was in this country.

Dr Bulkley, in closing, said that this method of treatment was not applicable to every case, nor should we simply limit the treatment to a vegetarian diet. In every case, other treatment was indicated as well, but the main factor was to cut off that kind of food which produced this condition.

Tuesday September 10—Second Day.

H. Radcliffe Crocker, of London, Vice-President, in the Chair.

The Pathology of Brown-tail Moth Dermatitis.—Dr E. E. Tyzzer of Boston, who read this paper, said the exact date of the introduction of the brown-tail moth into this country was unknown, but it was first noted in large numbers in 1897 in one of the suburbs of Boston. This species had since spread throughout the greater part of New England, and had also penetrated adjacent territory. It has been shown that the dermatitis which was produced by these insects was due to very minute, sharp-pointed, barbed hairs, the "nettling hairs" which developed on the caterpillar. The other hairs were harmless. On experimentation with the nettling hairs it was found that when they were mingled with a drop of blood a peculiar reaction took place which served as an index to their toxicity. The toxic principle was removed from the hairs by dilute alkalis and by water heated to 60° C., but it was insoluble in other common reagents. It was quite resistant to heat and withstood baking for one hour at 110° C., but was destroyed by baking at 115° C. The nettling hairs after such treatment no longer gave any reaction when mingled with blood, and produced no irritation when inoculated upon the skin.

Trauma as an Etiological Factor in Skin Diseases.—Dr. Neuberger of Nuremberg, Germany, read a paper on this subject, in which he emphasized the importance of trauma as an etiological factor in the production of certain diseases of the skin.

Dr. Joseph Zeisler of Chicago, in discussing Dr. Neuberger's paper, said this subject was not a new one. Thirty years ago Kaposi and his school had insisted that trauma might act as a focus in the production of various diseases of the skin, and this fact had been pointed out in connection with lichen planus, eczema, psoriasis, and even syphilis.

Dr. A. Ravogli of Cincinnati said that instances were not infrequent where trauma, either directly or indirectly, called attention to certain skin lesions or to a certain diathesis, as, for example, the occurrence of tuberculosis of the knee after injury .

Idiopathic Multiple Hemorrhagic Sarcoma (Kaposi). Dr. M. B. Hartzell of Philadelphia, in this paper, said that in 1872 Kaposi first called attention to an unusual and remarkable affection of the skin characterized by the occurrence of deeply pigmented infiltrated patches and small tumors, situated almost invariably on the extremities, followed after several years by visceral metastases and death, for which he proposed the name idiopathic multiple pigmented sarcoma, a name which he, twenty years later, changed to idiopathic multiple hemorrhagic sarcoma, as being more accurately descriptive of the disease. He regarded the malady as a typical, although special and peculiar, form of round-celled sarcoma, with the occasional occurrence of characteristic spindle cells. Soon after the appearance of Kaposi's paper other observers began to report similar cases and the list had steadily though slowly grown until the number of recorded cases was now something over one hundred. While the affection seemed to be peculiar to no country or race, the great majority of cases on record had been reported by European observers, and fully one-half of these were from the northern provinces of Italy. The number of cases reported in America was extremely small, and some of these occurred in foreign born. Dr. Hartzell then reported in detail a case of this affection which recently came under his observation.

Dr. H. Radcliffe-Crocker of London said that multiple idiopathic hemorrhagic sarcoma was an affection that was rarely met with in England.

Dr. Edward H. Shields of Cincinnati referred to a case of this character that he had observed in Kaposi's clinic.

Dr. Stevens of Detroit mentioned a case that he had seen at Ann Arbor about two years ago. The patient was a man seventy-two years old, a native of Michigan.

Multiple Benign Cystic Epithelioma (Demonstrated from **Lantern Slides**).—Dr. M. L. Heidingsfeld of Cincinnati presented this paper, in which he offered the following conclusions: 1. Multiple benign cystic epithelioma, lymphangioma tuberosum multiplex, and adenoma sebaceum were affections which possessed sufficient clinical and pathological variations to render many of the cases of doubtful recognition and classification. 2. These three affections were doubtless of embryonic misplaced tissue origin, and the clinical and pathological variations which were noted in each were sufficiently common to all to give them a common classification and thereby prevent a somewhat arbitrary, confusing, and redundant nomenclature. 3. Some of the clinical and many of the pathological changes had a striking resemblance to those manifested in early malignancy of the skin. 4. It was highly probable that malignancy of the skin, aside from other causal influences, also owed its direct origin to misplaced embryonic tissue.

Observations on Skin Diseases in the Negro.—Dr. Howard Fox of New York City read a paper on this subject, in which he advanced the following conclusions: 1. In spite of the fact that the negro was more susceptible to disease in general than the white man, and that his mortality was twice as great, he suffered less frequently and less severely from diseases of the skin. 2. The negro skin was decidedly less susceptible to external irritants. 3. The full-blooded negro was almost immune to ivy poisoning. 4. Acne was less common and much less severe in the negro. Rosacea was a rare and very mild affection. Eczema was perhaps not less frequent, though certainly less severe. Psoriasis in the full-blooded negro was very uncommon. 5. Tuberculosis of the skin was not more common in the negro, in spite of the great prevalence in this race of pulmonary and other forms of tuberculosis. 6. Syphilis was certainly more common in the negro than in the white. The acquired form was probably not more virulent, and tertiary forms were not more common. A tendency to the annular syphilide, as well as to keloid, elephantiasis, and fibroma deserved to be classed as a racial peculiarity of the negro. 7. The negro was more subject to new growths of connective tissue origin, and less so to those originating in epithelial structures. Cutaneous epithelioma was very rare in the full-blooded negro. 8. The mucous membranes, as well as the skin, were less susceptible to disease. Leucoplakia was seen in the negro with extreme rarity. 9. Many of the rarer forms of skin disease were observed in the negro, as well as in the white race. 10. Mulattoes were more susceptible to skin diseases than negroes, being especially prone to chloasma.

Dr. Isador Dyer of New Orleans said the social condition of the negro in the South was vastly inferior to that of his Northern brethren, and for that reason a comparison of the statistics between these two sections of the country would be of little value. In the South the negro as a rule did not apply for treatment for a skin condition unless it was disfiguring or caused him suffering. It was not unusual to have a negro present himself for some venereal disease, and reveal, upon examination, a variety of parasitic and other skin lesions. Dr. Dyer said the annular syphilide, as seen in the negro, especially in young children, was ofttimes partly vesicular. The observation had been made in New Orleans that perhaps the only malignant type of syphilis seen there occurred in the negro; it was exceptional in the white.

Dr. Joseph Grindon of St. Louis said he was surprised to hear that syphilis was milder in the negro than in the white man. His own experience had shown the opposite to be the fact. Negroes practically did not figure in private practice, and in dispensary practice they did not present themselves in the numbers that one would expect. Often they treated themselves or remained untreated.

ANATOMY.

Answer all questions.

1. Locate and describe fully the sternum.
2. Locate and describe fully the Trapezius muscle and give its relations.
3. Locate and describe the internal carotid artery of the right side, and mention its branches.
4. Locate and describe the thoracic duct.
5. Locate and describe the pancreas.
6. Locate and describe the heart.
7. Locate and describe the pneumogastric nerve, giving its origin and distribution.

PHYSIOLOGY.

1. Describe digestion fully from the time food enters the mouth until the residue is evacuated.
2. What are the principal functions of the hepatic cells?
3. Describe the coagulation of the blood and state what conditions favor it and what retard it.
4. Give the vital capacity of the lungs.
5. Explain the sounds of the heart and the cause of them.
6. What is the function of the sympathetic nervous system?
7. What special centers are located in the medulla oblongata?
8. What is the function of the anterior spinal nerve roots.

MATERIA MEDICA.

1. What is a disinfectant and how does it differ from a deodorant, where use the latter and where employ the former?
2. What is a Seidlitz powder?
3. What are the salines?
4. What is the use of sanguinaria?
5. What is ergot, how obtained, its physiological effects?
6. What is buchu and in what diseases is it employed?
7. Name some of the vegetable astringents.
8. What are narcotics and give the most important chemical constituents of opium.
9. What is lime water—effects and uses?
10. Electricity for medicinal purposes is obtained from what sources?

CHEMISTRY AND TOXICOLOGY.

1. Name the halogens and describe one of the group.
2. Define the following terms and give an example of each: (a) Water of crystallization. (b) Binary compound. (c) Double salt. (d) Double decomposition.
3. Express by equations the chemical reactions when the following substances are combined: (a) Barium dioxide and sulphuric acid. (b) Slaked lime and sal ammoniac. (c) Lead acetate and sulphuretted hydrogen.
4. Give the chemical test for free HCl in gastric contents, and write equation to show reaction.
5. Describe the diazo reaction and give its diagnostic value.
6. Name five vegetable poisons and an antidote for one of them.
7. What is carbolic acid, chemically speaking? Name an antidote for it.
8. How would you detect arsenical poisoning? Give treatment for a case.
9. Give treatment for poisoning by swallowing mercuric chloride.
10. Describe a case of opium poisoning.

HISTOLOGY.

1. Describe the structure of bone.
2. Describe the structure of a medium sized artery.
3. Give the histology of cardiac muscle.
4. Give the classification of glands (as to structure) found in the skin and mucous membrane. Mention examples of each.
5. Describe the microscopical appearance of the section of a nerve trunk.

PATHOLOGY.

1. Define (a) Necrosis, (b) Hyperemia, (c) Edema.
2. Define a tumor. How does it differ from hypertrophic tissue?
3. What pathological changes occur in the liver and pancreas in diabetes?

4. What is inflammation?
5. Define sarcoma and name varieties.

PRACTICE OF MEDICINE.

1. Define pertussis and give incubation period and treatment.
2. Give etiology, symptoms, and treatment of diabetes mellitus.
3. Give etiology, symptoms, and treatment of multiple neuritis.
4. Give cause and symptoms of biliary colic and differentiate from appendicitis.
5. Give treatment with prescriptions for a case of acute articular rheumatism.

OBSTETRICS.

1. Give, in order of their appearance, the signs and symptoms of pregnancy, subjective and objective.
2. Give causes, symptoms, and treatment of phlegmasia alba dolens.
3. Treatment: (a) Threatened abortion.
(b) Inevitable abortion.
4. Symptoms and treatment of placenta prævia.
5. Describe your first case of labor.

DISEASES OF WOMEN AND CHILDREN.

1. How would you repair the perineum?
2. What symptoms may follow displacement of the uterus?
3. How would you diagnose inflammation of the tubes, and what is the most common cause?
4. How would you treat an acute gonorrhea in the female?
5. Give causes of suppressed menstruation and your treatment.
6. Give directions for feeding an infant three months old with artificial food.
7. Give causes and treatment of simple croup.
8. Name causes for infantile convulsions.
9. Give treatment for intestinal worms.
10. Diagnosis between tonsillitis and diphtheria.

SURGERY.

Answer any six questions.

1. In what sex does femoral hernia most frequently occur? Describe operation for cure.
2. Describe operation for gallstones.
3. (a) Give briefly the preparation of a patient and surgeon for an abdominal operation. (b) Locate the attached or cecal end of the appendix on the abdominal wall.
4. Indicate a treatment for hemorrhoids. (a) Palliative. (b) One operative method.
5. (a) What is meant by aseptic? (b) Antiseptic. (c) What is the best method of rendering surgical instruments aseptic? (d) In what strength should bichloride of mercury be used as a lotion? (e) Carbolic acid. (f) What is necessary to render ordinary water sterile?
6. Give diagnosis and treatment of floating kidney.
7. Give symptoms and treatment of fracture of the base of the skull.
8. Name the different forms of sutures, and describe the Glover's suture.
9. Give the signs, symptoms, and approved treatment of fracture of the patella.
10. How would you prepare a patient for anesthesia?

PREVENTIVE MEDICINE.

1. What are the chief causes and what the means of preventing dysentery and diarrhea?
2. Give the cause of scurvy and the method of prevention and cure.
3. What causes military ophthalmia and when it prevails how treat it? Can it be cured?
4. Give the measures to be taken for the prevention of venereal diseases.
5. Is phthisis pulmonalis hereditary or acquired, and what three points in its treatment are essential and most effective?

NERVOUS DISEASES.

1. Give the causes, symptoms, diagnosis, and treatment of epilepsy.
2. Define the terms: Insanity, delusion, illusion, hallucination.
3. Give causes, symptoms, diagnosis, and treatment of acute transverse myelitis.
4. What is chorea? Give causes, diagnosis, and treatment.
5. Differentiate between cerebral hemorrhage, uremic coma and alcoholic coma.

EYE AND EAR.

1. What is ophthalmia neonatorum? Give treatment.
2. What are the diagnostic differences between conjunctivitis and iritis? Give treatment of each.
3. What are the causes, symptoms and treatment of chalazion?
4. Describe fully the effect of nasopharyngeal adenoids on the ear and its function.
5. What are the symptoms, etiology, and treatment of mastoiditis?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE MEDICAL EXAMINING BOARD OF NORTH DAKOTA.

Grand Forks, July 2 and 3, 1907.

PHYSIOLOGY.

2. The principal functions of the hepatic cells are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

3. When blood is withdrawn from the blood-vessels of the living body, it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats in the serum. The process is thus summed up by Halliburton: In the plasma a proteid substance exists, called Fibrinogen. From the colorless corpuscles a nucleo-proteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot.

Conditions *favoring* coagulation of the blood are: (1) Moderate warmth, (2) contact with foreign matter, (3) agitation, (4) the presence of calcium salts.

Conditions *retarding* coagulation of the blood are: (1) A low temperature, (2) the addition of neutral salts in large quantities, (3) contact with oil, (4) contact with the living vessel walls, (5) when mixed with an oxalate, (6) the injection of peptones or lead extract.

4. The vital capacity of the lungs is about 225 to 250 cubic inches.

5. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

6. The *functions* of the sympathetic nervous system: "It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor-nerves), are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or less extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*."—(*Reference Handbook of the Medical Sciences.*)

7. The special centers located in the medulla oblongata are: (1) Center for mastication, (2) for secretion of saliva, (3) for sucking, (4) for deglutition, (5) for vomiting, (6) for voice, (7) center for expression, (8) cardiac centers, (9) respiratory centers, (10) vasomotor centers.

8. The *function* of the anterior spinal nerve roots is: Motion, to the muscles which they supply.

MATERIA MEDICA.

1. A *disinfectant* is an agent or substance which restrains infectious diseases by destroying or removing their specific poisons.

A *deodorant* is a substance which destroys the odorous products of putrefaction.

A *deodorant* is indicated when there is simply a foul odor to be disposed of.

A *disinfectant* is indicated where disease germs are present.

2. A Seidlitz powder consists of: (1) Potassium and sodium tartrate, gr. cxx, and sodium bicarbonate, gr. xl; these are mixed and put in one paper. (2) Tartaric acid, gr. xxxv, in another paper. The dose is one or two of each of these dissolved separately in water and the solutions poured together.

3. Salines are purgatives composed of the neutral salts of metals of the alkalies, or of the alkaline earths. The salines are: Magnesium sulphate, magnesium citrate, sodium sulphate, sodium phosphate, sodium chloride, sodium and potassium tartrate, potassium tartrate, potassium bitartrate, and potassium sulphate.

4. Sanguinaria is used to cause sneezing, to produce salivation, purging, vomiting; in small doses it is an expectorant.

5. Ergot is the sclerotium of the Claviceps purpurea. It should be moderately dried, preserved in a close vessel, and a few drops of chloroform should be dropped upon it occasionally. It is not fit for use if more than a year old.

Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

6. Buchu is the leaves of the *Barosma betulina*. It is employed in chronic inflammatory conditions of the genito-urinary tract as cystitis, urethritis, pyelitis; also in chronic bronchitis, uric acid diathesis, prostatic inflammation, and dyspepsia.

7. Vegetable astringents: Gallotannic acid, nut galls, hamamelis, catechu, kino, krameria, hematoxylon, granatum, quercus alba.

8. Narcotics are agents which induce stupor or sleep, and at the same time are capable of relieving pain.

The most important chemical constituents of opium are: Morphine, narcotine, codeine, thebaine, papaverine, and meconic acid.

9. Lime water is a solution of unslaked lime in water. It is an antacid, a mild astringent, and assists in the formation of bone.

It is used in nausea and vomiting due to gastric acidity; to aid in the digestion of milk; in diabetes; in uric acid diathesis. It has been applied to the membrane in diphtheria; and externally, in tinea capitis, and (mixed with olive or linseed oil) in burns.

10. Electricity for medicinal purposes is obtained from the following sources: Current from electric light mains, dynamo and driving plant, accumulators, primary batteries.

CHEMISTRY AND TOXICOLOGY.

1. The halogens are: Fluorine, chlorine, bromine, and iodine.

Chlorine exists only in combination, chiefly in sodium chloride. It is a greenish yellow gas, very irritant, and with a penetrating odor. It tends to combine with other elements, and such combination may be attended with the giving off of heat and light, or an explosion. With hydrogen it combines in the light to form hydrochloric acid. In the presence of water it is an active bleaching and disinfecting agent. Its atomic weight is 35.5, and its valence one.

2. (*a*) *Water of crystallization* is the water necessary, in many crystals, to the maintenance of the form, and sometimes the color, of the crystal. Example: $FeSO_4+7Aq.$ denotes ferrous sulphate with seven molecules of water of crystallization.

(*b*) A *binary compound* is a compound composed of two elements only. Example: NaCl, sodium chloride.

(*c*) A *double salt* is a salt formed by the substitution of different elements or radicals for two or more atoms of the replaceable hydrogen of an acid. Example: $NaKC_4H_4O_6$, sodium potassium tartrate.

(*d*) *Double decomposition* is a reaction in which both of the reacting compounds are decomposed to form two new compounds. Example: $CuSO_4+H_2S=H_2SO_4+CuS$.

3. (*a*) $BaO_2+H_2SO_4=BaSO_4+H_2O_2$.

(*b*) $CaH_2O_2+2NH_4Cl=CaCl_2+2NH_3+2H_2O$.

(*c*) $Pb(C_2H_3O_2)_2+H_2S=PbS+2C_2H_4O_2$.

4. There are three or four chemical tests for free HCl in gastric contents; the best is probably the Dimethylamido-azobenzol test. The reagent is used in 0.5 per cent. alcoholic solution, of which one or two drops are added to a like amount of the filtered gastric juice. If free HCl is present, the yellow solution turns red.

5. For the diazo reaction two solutions are required: (1) A saturated solution of sulphanilic acid in a mixture of 50 c.c. of hydrochloric acid and 950 c.c. of water; and (2) a 0.5 per cent. solution of sodium nitrite.

To make the test, 1 c.c. of (2) is added to 40 c.c. of (1), and the mixture thoroughly shaken. Equal quantities of this mixture and the urine to be tested are shaken together in a test tube, and 1 c.c. of ammonia is then floated upon the surface, when, in an affirmative result, a red band is formed at the junction of the fluids.

Its diagnostic value is uncertain. Von Jaksch "disclaims for this test any clinical importance whatever." Others have claimed that the reaction is pathognomonic of typhoid; but it has been found in other diseases besides typhoid—namely, phthisis, pneumonia, measles, scarlet fever, smallpox, and malaria.

6. Five vegetable poisons: Aconite, belladonna, strychnine, opium, and digitalis; tannic acid is said to be the chemical antidote for digitalis.

7. Chemically speaking, carbolic acid is phenol, or phenyl hydroxid, C_6H_5OH.

The antidote for it is sodium sulphate, or alcohol.

8. *Test for arsenic*: Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

Treatment consists in giving zinc sulphate to induce vomiting, syphoning out the stomach, and administering freshly prepared solution of ferric hydroxide.

9. The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

10. In opium poisoning there may be three stages: (1) A period of excitement, in which the patient is active, talkative, and has hallucinations; (2) a period of drowsiness, in which the patient is sleepy, but may be aroused; his face is pale, lips livid, pupils contracted; this passes into (3) the stage of coma, from which the patient cannot be aroused, the reflexes are abolished, the pupils are very contracted, the pulse is slow and irregular, and the respirations are infrequent and shallow.

HISTOLOGY.

4. I. Simple glands.—Duct undivided.

(*a*) *Simple tubular.*—Undilated at end—*e.g.* Lieberkühn's follicles, sweat, and many gastric glands.

(*b*) *Simple acinous* (*alveolar or saccular.*)—Dilated at end—*e.g.* some sebaceous glands (rare).

II. Compound glands.—Duct divided.

(*a*) *Compound tubular.*—Branched elongated tubes, no acini—*e.g.* most gastric glands.

(*b*) *Compound acinous or alveolar* (*racemose glands*), branched duct with saccular acini on terminal branches—*e.g.* salivary, sebaceous, and Meibomian glands; the mucous glands of the mouth, tongue, palate, pharynx, nose, esophagus, and respiratory tube.

(*c*) *Acino-tubular.*—Branched duct, with elongated narrow acini on terminal branches—*e.g.* Brunner's glands.

(From Cunningham's *Anatomy.*)

PATHOLOGY.

1. (a) *Necrosis* is the complete and permanent arrest of nutrition in a part; or local death of tissues.

(b) *Hyperemia* is excess of blood in a part of the body.

(c) *Edema* is excess of liquid in the connective tissues of the body.

2. A *tumor* is an atypical new formation, not the result of inflammation, and which has no physiological function. A tumor differs from hypertrophic tissue in that the latter retains its original structure, shape, and function.

3. In diabetes: The *liver* is enlarged, and may undergo fatty degeneration or become sclerotic. The *pancreas* may not be affected at all, or there may be an interstitial pancreatitis, or there may be degenerative changes in the islands of Langerhans, or the pancreas may be atrophied. It is probable that the diabetes is due to disease of the pancreas, and not *vice versa*.

4. *Inflammation* has been defined: (1) As the succession of changes which take place in a living tissue as the result of some kind of injury, provided that this injury be insufficient immediately to destroy its vitality.

(2) As the reaction of tissues to an injury.

5. A *sarcoma* is a malignant tumor of the connective tissue type, in which there is abundant cell formation with very scanty intercellular substance.

Sarcomata are classified:

I. According to the *form of the cell* which predominates, as Round-cell, Spindle-cell, and Mixed-cell sarcomata.

II. According to the *stroma*, as Myxo-sarcoma, Chondro-sarcoma, Fibro-sarcoma, and Osteo-sarcoma.

III. According to the *secondary changes* which they may undergo, as Lipo-sarcoma, Chloroma, Melano-sarcoma, and Calcifying sarcoma.

OBSTETRICS.

1. The *subjective* signs of pregnancy, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

The *objective* signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heart-beat, rate of growth of the uterine tumor.

DISEASES OF WOMEN AND CHILDREN.

2. The following symptoms may follow displacements of the uterus: Backache, bearing-down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances, as dysmenorrhea or menorrhagia, sterility; there may also be *general symptoms*, as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise.

3. Inflammation of the tubes is diagnosed by: A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesions; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain.

The most common cause is infection, either gonorrheal or puerperal.

4. Acute gonorrhea in the female requires: Rest, if possible in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5,000 bichloride solution, or of borax (1 dram to the quart); the douche is to be taken in the recumbent position.

5. The causes of suppressed menstruation are: Pregnancy; lactation; severe physical or mental shock; obesity; taking cold near the time of a menstrual period; certain diseases, such as typhoid, tuberculosis, pneumonia, diabetes, nephritis, anemia, chlorosis, syphilis, sepsis; change of climate; absence, lack of development, malformation, atresia, disease, or removal of some part of the genital tract; hysteria, and various mental disorders.

6. For a child three months old:

℞. Cream ℥ss (one tablespoonful)
Milk ℥iss (three tablespoonfuls)
Water ℥iss (three tablespoonfuls)
Milk sugar ℥j (one teaspoonful)
Salt gr. v. (a pinch).

Feed every two and a half hours.

8. Causes of infantile convulsions are: "Overeating, especially of indigestible food; rachitis, debility from exhausting diarrheal diseases; high fever, especially at the onset of the acute specific infections; very seldom dentition, phimosis, and acute middle-ear inflammation; injuries to the brain at birth, infantile hemiplegia, meningitis, and tumor of the brain; rarely of spinal cord disease."—(From Butler's *Diagnostics of Internal Medicine.*)

9. *Treatment of tapeworm*: Give a dose of castor oil at night, and the following morning give half a dram of freshly prepared extract of male fern, and a few hours later give another dose of castor oil.

Treatment of roundworm: A dose of santonin and calomel should be given at bedtime for a few nights, and a dose of castor oil the morning after the last powder.

Treatment of seatworm or pinworm: A large enema of a cold infusion of quassia. Care must be taken to prevent reinfection

10.

TONSILLITIS.	DIPHTHERIA.
1. Sudden onset.	1. More gradual onset.
2. Chill.	2. Chill is rare.
3. Temperature 103° to 105° F.	3. Temperature 101° to 103° F.
4. Vomiting is occasional.	4. Vomiting is common.
5. Albuminous urine rare.	5. Albuminous urine common.
6. Tonsils considerably enlarged.	6. Tonsils not much enlarged unless chronic hypertrophy of the tonsils previously existed.
7. Exudation in spots or a pseudomembrane.	7. Exudation, a thick membrane.
8. Pseudomembrane margins are the same color as the rest of the mucous membrane of the tonsil.	8. Diphtheritic membrane margins are dark red or purplish in color for a distance of a quarter of an inch.
9. Pseudomembrane not adherent; easily wiped away with cotton.	9. Membrane very adherent; removed with difficulty, and only with forceps.
10. Leaves no bleeding surface.	10. Denuded surface bleeds.
11. Pseudomembrane does not re-form.	11. Membrane re-forms in a few hours.
12. Pseudomembrane limited to the tonsil.	12. Membrane also found on the pillars of the fauces, the soft palate, and posterior pharyngeal wall.
13. Intense active hyperemla of the soft palate.	13. Soft palate almost normal in appearance.
14. Bacteriological examination shows staphylococci, streptococci, and pseudodiphtheria bacilli.	14. Bacteriological examination shows Klebs-Loeffler bacilli.

(From Coakley's *Diseases of the Nose and Throat.*)

SURGERY.

3. (b) Draw a straight line on the abdominal wall from the anterior superior spine of the ilium to the umbilicus; on this line, and about one and a half or two inches internal to the anterior superior spine, the cecal end of the appendix should be found.

4. (a) The *palliative* treatment of hemorrhoids consists in: The use of unirritating laxatives, to prevent constipation; cleansing the parts; rest; application of heat or cold or applications of opium or gall.

(b) The *operative* treatment consists in: Crushing with a clamp and then removing with a cautery; or complete resection of the mucous membrane; or they may be cut off after ligation or crushing.

5. (a) *Aseptic* means sterile, entire absence of germs or their products.

(b) An *antiseptic* is an agent that destroys microorganisms. The object of antisepsis is to produce asepsis.

(c) The best method of rendering surgical instruments aseptic is by boiling them for about fifteen minutes in water, each quart of which contains a tablespoonful of sodium carbonate.

(d) As a lotion, bichloride of mercury can be used in strengths varying from 1:10,000 to 1:500.

(e) Carbolic acid in strength varying from 1:60 to 1:40.

(f) To render ordinary water sterile, first filter it, then boil for half an hour, and place it in sterilized glass containers, the mouths of which are to be covered with several thicknesses of sterile gauze.

8. The different forms of sutures are: The interrupted, continuous, buried, chain-stitch, mattress or quilt, subcuticular, twisted or hare-lip, quilled, shotted, button or plate, Lembert's, Czerny, Halsted's, purse-string, relaxation and coaptation.

Glover's suture is the same as the continuous suture; it is made by passing the threaded needle through the skin about an eighth to a quarter of an inch from the edge of the wound. The needle is then passed from within outwards through the tissues of the opposite flap, at the same distance from the edge of the wound. This is done repeatedly, as often as the size of the wound requires; the

thread is not cut till after the last stitch is passed, and knotted.

PREVENTIVE MEDICINE.

3. *Military ophthalmia* is purulent conjunctivitis, due to contagion from gonorrheal virus. It is caused by the gonococci.

"Treatment.—Prophylactic: Great precautions must be observed to prevent infection of the eyes of the physician, nurse, and attendants through spurting of the discharge during examination or treatment; protecting glasses should be worn whenever exposed to this risk. Contaminated fingers must be carefully disinfected. Materials which have been used for cleansing the eye must be burned.

"The non-affected eye should be protected from infection by the application of Buller's shield. This consists of a watch glass, securely held in place by adhesive plaster applied to the side of the nose, the cheek, and forehead. The junction of skin and plaster is sealed by a layer of collodion. The center of the glass is left uncovered by plaster to permit inspection of the eye, and a small part of the outer margin of the watch glass is usually left free in order to allow air to enter and contribute to the comfort of the shielded eye.

"Treatment of the first stage: Iced compresses are used continuously, day and night. The eye must be carefully cleansed and the secretion removed as rapidly as it forms. When very abundant, this will be necessary every quarter or half an hour. For this purpose a saturated solution of boric acid is most frequently employed, being allowed to trickle in between the lids from a piece of absorbent cotton dripping with the solution; then the secretion which has been washed out is gently wiped off the margins of the lids.

"The iced compresses may be used continuously at first. But when the tense, reddened, and swollen condition of the lids becomes less marked the application of cold must be reduced to every other hour, or every third hour; too much refrigeration interferes with the nutrition of the cornea. When the cornea is involved, we must carefully gauge the amount of cold so as not to use an excess. In the later stages, when there is little swelling, and corneal infiltration or ulceration exists, hot applications may be indicated. . .

"In the initial stage, if the disease be very severe, from three to six leeches, applied to the corresponding temple, may be of service. Occasionally there is so much tension that the eye cannot be cleansed on account of the difficulty in separating the lids, and in addition harmful pressure is exerted upon the eyeball; in such cases it may become necessary to widen the palpebral fissure by a division of the external canthus.

"Treatment of the Later Stages: When the lids have lost their swollen and angry appearance and the discharge begins to diminish, a one or two per cent. solution of nitrate of silver is brushed upon the everted conjunctiva once a day. This may be done even though the cornea is implicated. It is continued until the patient is well, or until the papillary swelling has persisted for some time. Then, if silver no longer exerts a favorable influence, we may apply glycerole of tannin (five to ten per cent.), the alum stick, or sulphate of copper pencil once a day."

"Prognosis depends upon the severity of the case, and upon the behavior of the cornea. It is always grave." (May, *Diseases of the Eye.*)

NERVOUS DISEASES.

2. According to Taylor, the term *insanity* is applied to "those states of disordered mind in which a person loses the power of regulating his actions and conduct according to the ordinary rules of society. In all cases of real insanity the intellect is more or less affected."

A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion*. If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion*. If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination*.

5. In *cerebral hemorrhage*:—There is generally paralysis of the head and upper limbs; and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

In *uremic coma*:—The coma is deep; the pulse slow; the respirations frequent and irregular; the urine shows the presence of albumin and casts, with a diminished output of urea; there may be a urinous odor to the breath.

In *alcoholic coma*:—The patient can generally be aroused; the coma is not, as a rule, complete; the face may be flushed; the pupils are normal or dilated; the respirations are normal in frequency, but deep; the skin is cool and moist, and the body temperature may be below normal.

EYE AND EAR.

1. Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the new-born.

It is due to the gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

The treatment is:—(1) Prophylactic—whenever there is the possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial*:—Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

2.

CONJUNCTIVITIS.	IRITIS.
1. No change in iris.	1. Discolored and altered iris.
2. Pupil normal.	2. Pupil small, gray, sluggish, irregular after use of atropine.
3. Anterior chamber normal.	3. Exudation in anterior chamber.
4. Conjunctival injection, coarse meshes, most pronounced in fornix and fading toward the cornea.	4. Ciliary (circumcorneal) injection; pink zone of fine vessels surrounding cornea and fading toward fornix.
5. Mucous or muco-purulent secretion.	5. Lacrymation, but no secretion.
6. Discomfort, but no real pain.	6. Pain, worse at night.
7. Conjunctiva reddened and opaque.	7. Conjunctiva usually transparent.
8. No interference with vision.	8. Vision diminished in acuteness.

(May's *Diseases of the Eye.*)

4. "The presence of adenoid tissue in the vault of the pharynx affects the ear in two ways. If the mass is large by direct pressure upon the Eustachian orifice the supply of air in the tympanic cavity may be disturbed. . . . Any slight increase in the volume of the mass will close the lumen of the tube, after which the intratympanic air is gradually absorbed by the blood which circulates through vessels in the walls of the cavity. With each act of swallowing, at which time the tube opens momentarily, the air is aspirated into the nasopharynx, the tube closing so quickly that the passage of air into the tympanum does not take place. In this manner a passive congestion of the mucous membrane of the middle ear is produced, a condition which constitutes practically the first stage of an inflammation, and, if long continued, results in permanent tissue changes. . . . The more important manner in which adenoid growths affect the organ of hearing is by the obstruction to the venous return current from the tympanum and labyrinth. The pharyngeal tonsil, in virtue of its presence, may exert sufficient pressure to partially obstruct the venous flow from the tympanic cavity. Any condition which affects, for a considerable period, the circulation within the middle ear will also cause a disturbance of the labyrinthine circulation from an alteration in the tension of the fluid contained. Such changes in the labyrinth render it particularly susceptible to inflammation, either as the result of infection or of mechanical irritation, the most fruitful source of the latter being the crowding inward of the ossicular chain by atmospheric pressure, when the tension of air within the tympanum is reduced. . . There may also be a diminution of bone conduction and a hyperesthetic condition of the auditory nerve." (From Dench's *Diseases of the Ear.*)

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Alabama.—On the 1st day of September a new law regulating the practice of medicine in Alabama went into operation. The principal changes made in the old law are: The privilege of examining applicants has been withdrawn from County Boards, therefore all examinations will hereafter be held by the State Board. At least two examinations shall be held annually. The branches upon which applicants will be examined are: Anatomy; chemistry; physiology; the etiology, pathology, and symptomatology of diseases; surgery; obstetrics and obstetrical operations; gynecology; physical diagnosis; hygiene and medical jurisprudence; diseases of the eye, ear, nose, and throat. A diploma will not be required as a prerequisite for examination. All persons who desire to practise medicine in this State must be examined, irrespective of any certificates of qualification, obtained elsewhere, they may hold. At least three days will be required to complete the examination. The first examination under the new law will begin on Tuesday, October 1, at 9 o'clock A.M., in the Capitol at Montgomery. Persons contemplating presenting themselves for examination at that time should give notice of such intention. The fee for examination will be $10.00, payable in advance. All applicants, of whatsoever school of practice, will undergo the same examination. Materia medica and the administration of drugs in disease are omitted from the examination.

South Carolina.—This State reciprocates with Illinois, Kansas, Maine, Maryland, Michigan, Minnesota, Missouri, Nevada, Texas, Utah, Virginia, West Virginia, Wisconsin and Wyoming. No application for license to practise in South Carolina based upon a license to practise in a sister State, will be considered unless the applicant has resided at least one year in the State granting the original license.

Minnesota.—This State reciprocates, under certain conditions, with the District of Columbia, Indiana, Iowa, Kansas, Maine, Maryland, Michigan, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, Ohio, South Carolina, Tennessee, Texas, Utah, Virginia, Wisconsin and Wyoming.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagions diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 21, 1907:

	Cases	Deaths

URIC ACID SYMPTOMS (RHEUMATISM) AND THEIR RELIEF BY COLCHICUM AND THE SALICYLATES.

By A. H. P. LEUF, M.D.,

PHILADELPHIA.

It is safe to preface this paper with the statement that the cause of excessive uric acid formation is not known, and the symptomatology of the condition is not understood except along certain lines.

Uric acid in the urine is usually associated with the term "rheumatism," one of the designations behind which masquerade a number of clinical entities probably due to a variety of causes, but which have not yet been differentiated. Uric acid conditions or diatheses have thus come to be considered synonymous with rheumatism, at least with its more chronic manifestations. In this paper I may use the terms interchangeably because of the mental habit of their association, but by the term "rheumatism" I wish to be understood as meaning the condition of an excess of uric acid in the body, usually indicated by uric acid crystals or detritus or amorphous urates in the urine, generally in abundance, though sometimes totally absent, for a time at least, or nearly so.

The future will probably resolve many different "rheumatisms" into their separate clinical entities. However, they may prove to be changing signs of the same general cause, difference in manifestations being merely incident to varying parts of the organism responding most adversely to influences of the pathological state. That this is feasible is demonstrated, for instance, by syphilis, in which the same cause produces a host of varying symptoms, many even in the same individual.

The uric acid state may affect perceptibly almost any tissue or part of the body, most prominent among which may be mentioned joints, ligaments, muscles, skin, throat, teeth, eyes, ears, urethra, intestines, the serous membranes generally, the excretory mucosæ, and the nervous system.

We are too apt to limit evidence of "rheumatism" to uric acid conditions in joints or fibrous structures and voluntary muscles and the cardiac membranes. In view, however, of the well-known effect upon joints, ligaments, tendons, and the faucial mucosa, why should any tissue be exempt? Whatever may be the local cause of pain, it probably acts upon the most susceptible part of the organism, and that this may exceptionally be a tissue usually exempt is not at all improbable. This supposition has the advantage, at all events, of being a good working hypothesis, there being no known facts to contradict it.

Uric Acid "Rheumatism" Defined.—Let us, then, assume that "rheumatism" is that clinical condition of local pain, generally shifting, though not always, otherwise unaccountable, and accompanied by the presence of uric acid crystals or detritus or amorphous urates in the urine, and which is marked by susceptibility to cold and damp and weather changes, or which, despite the absence of the characteristic urinary deposit, nevertheless yields promptly to colchicum and the salicylates. As a rule, uric acid may readily be found in afflictions of this kind yielding to these two remedies, and when not in evidence in the urine does, however, exist in the blood, where its detection is not so easy for the general practitioner. Prompt yielding of such symptoms to colchicum, the salicylates, alkalies, and salines, seems to me to be good therapeutic evidence of rheumatism, certainly as much so as is yielding to mercury and potassium iodide of syphilis, and to quinine of malaria.

Articular, ligamentous, and muscular involvement is so commonly appreciated that these forms require no attention in this paper.

Cutaneous Rheumatism.—This is fairly well known by its urticarious symptoms of pruritus and hyperemia patches. It is stubborn to all local and internal medicinal treatment, except that which is efficient in rheumatic conditions, and that will hasten the elimination, and prevent excessive formation, of uric acid. The best local easement often follows the use of sodium bicarbonate, in the form of a wash as well as internally administered. Diet is also a help in removing the trouble. Sometimes the urticaria is the only symptom complained of, or, on the other hand, it may not be present in other rheumatic states, and only appear as the result of salicylic medication. This should be remembered lest the attempt is made to cure a drug trouble by the very remedy that is its cause.

Rheumatic Sore Throat.—Just as we have irritative urticaria of the external integument, so may we have a corresponding hyperemia of the inner skin, the mucous membrane. Probably the commonest occurrence of this kind is rheumatic sore throat. There is no exudate and no pus formation, but the membrane is a decided red, often rather dark, and is markedly aggravated by weather conditions that increase rheumatic symptoms. Local treatments, and even the usually successful internal medicines for ordinary sore throat, are inefficient except that the former somewhat allay pain if they contain anodynes. But the salicylates and colchicum cause a prompt and marked improvement. I have met with these so often that it seems unnecessary to cite illustrative cases for they must be quite common in the practice of all physicians who are even moderately busy.

I will, however, cite a single instructive instance, that of J. B., aged 15 years, U. S., almost six feet in height, and well built, whose father I was attending for a rheumatic synovitis of the right knee in April, 1900. The boy complained of sore throat, which I examined by request, finding it a dusky, angry red and painful; there was general hyperpyrexia, and the local trouble was unrelieved by home remedies that usually proved satisfactory. I ordered wine of

colchicum (gtt. x every 5 hours), and requested a sample of his urine. This contained enormously large crystals of uric acid in great abundance. Next day his throat felt better. He stopped his medicine, and there was a recrudescence of throat symptoms, but he neglected to take any more colchicum, though I warned him and his parents that he was on the verge of a volcano and in imminent danger of a severe acute rheumatic attack. He neglected the advice, and three days later awoke with a most severe acute inflammatory rheumatism. Even slight movement of any part of his body caused him to cry out loudly in evident excruciating pain. When he was moved to attend to calls of nature he cried loudly and uncontrollably with pain. It required large doses of morphine hypodermically to relieve him. The urine showed the same uric acid content. He took gtt. xii. of the wine of colchicum root every three hours, together with a lithia tablet (gr. v.) four or five times a day, and remained in bed ten days, when he felt quite well. But the colchicum was continued several days longer (gtt. v., t.i.d.) as a precautionary measure, and he kept his bowels freely open with magnesium sulphate.

Irritable bladder, from the presence of uric acid crystals, comes under my notice at frequent intervals. In such the diagnosis is assured by the absence of any other cause, the presence of uric acid in the urine, and the prompt relief of vesical irritability upon the disappearance of uric acid from the urine following the use of colchicum, or of it and the salicylate of sodium.

Acute urethritis, due to uric acid or oxalate of lime crystals, or both, in the urine, exists much oftener than one would suppose, judging from the literature. In fact, we are generally given to understand that a simple urethritis is rare, so that every one thus afflicted is at once more than under the ban of suspicion. The presumption in most instances is tantamount to a moral certainty of venereal infection. That this is decidedly wrong is one of the conclusions justified by my experience. I have cured "clapp" many times within a few days by diet and injection when it really was a simple irritative urethritis. And yet (such is the perversity of human nature) most such patients insisted that they must have the venereal disease, wish probably being father to the thought, for there are many who are inclined to pride themselves upon so undesirable a possession, or prefer to think that they have had it. However, there can be no doubt of the innocence of a urethritis when it is accompanied by uric acid and oxalate of lime crystals in the urine, and that is cured promptly by the use of colchicum and sodium salicylate, coincident with the diminution and disappearance of the crystals from the urine. The following is one such case to serve in illustration:

L. C., married, U. S., mill hand, had been subject to a slight urethral discharge from February, 1897, with occasional intermissions, for nearly a year. At times there would be merely agglutination of the meatus in the morning, followed by a drop of pus. At other times the discharge was more decided. Micturition was painful and burning, and at times accompanied by a sensation of passing something. This he interpreted as a coming small stone, and several times held his hand to receive it, but it never came. He had no chordee, and coitus was not always painful. He had noticed brick dust sediment in his urine. His wife was under treatment by me at the time thrice weekly, receiving intravaginal bipolar electrization for intrapelvic trouble. Her vaginal mucosa and cervix and os uteri were typically normal all the time. I had her under observation for a period of many weeks before and after I treated her husband, and can say, therefore, that she showed no sign of infection, though subject to regular coitus with him. His urine contained uric acid and oxalate of lime crystals in abundance. He took the wine of colchicum root (gtt. v. every five hours) and sodium salicylate (gr. v. every six hours). Nitrogenous foods were used sparingly, and beer and ale eschewed altogether. Seven days of this medication and regimen cleared up his urethral discharge and pain without injections.

He had two subsequent attacks in November, 1900, and May, 1902, both yielding to the same simple treatment. I may add that he had been receiving the usual injection and internal treatment before coming to me the first time.

Ocular Rheumatism.—This may be well known to the specialist, but it is quite a stranger to the general practitioner. I recall several instances in my experience within the past few years. One was that of a young man of 25, a chronic rheumatic, who had his glasses changed several times within one year by a specialist in whom he had unbounded confidence. He was astigmatic and wore compound cylinders. But none of his glasses were satisfactory. His vision remained defective, though not much, while his eye and brow pains were severe. Finally I prevailed upon him to submit to active medication with sodium salicylate and wine of colchicum, for his urine contained a considerable quantity of uric acid crystals. After a single week of this treatment he could see as well as ever with his old glasses, and his pain left him entirely. This experience was repeated with him on three subsequent occasions, except that he applied to me promptly without first seeing a specialist. His favorable response to moderate doses of these two agents was prompt every time, and was accompanied by lessening of the amount of uric acid in the urine.

Another instructive case, which I will cite more in detail, is that of M. F. B., U. S., 2½ years of age, who came to me July 10, 1905, with marked photophobia and slight conjunctival catarrh. She was malnourished. The belly was very prominent, soft, and contained much gas. She was nervous, fidgety, and capricious, whining a great deal. Her urine was said to be loaded with material that stained her clothes reddish and that left a crust on the sides and bottom of the chamber. She was very costive and her stools were dry. She ate little, and was under the care of an aunt, a very intelligent and experienced woman, who had taken her to several other physicians without benefit, one being an eye specialist. The patient kept her lids tightly closed, with her hands before them and her head bent down, even in a poor light. I ordered calomel for her bowels and a diet yielding a liberal residue for bowel stimulation. A nitrate of silver collyrium (gr. i. to the ounce) was to be used morning and evening, and I also ordered wine of colchicum root (one drop three times a day).

She lived out of town and could not see me again till August 21. Meanwhile I had examined her urine sent by mail, and found it loaded with enormous uric acid crystals. The aunt had been advised by mail to push the colchicum, which she did. An aphthous sore mouth developed and prevented much eating. At the time of her second visit her eyes were normal except for a small opacity over the center of the left pupil. She had daily stools, and her nervous system was in a normal condition. She was, however, ordered a continuance of the colchicum in single-drop doses thrice daily, together with the same amount of the oil of gaultheria.

July 27, 1906, she returned with her old eye

trouble worse than ever, having had it since the preceding April. Meanwhile she had been to two local physicians, had seen two specialists in Washington, D. C., while on a visit there, and was finally taken to the Wills Eye Hospital in this city, but without any improvement whatever. The aunt told all who saw her of the former successful treatment and the condition of her urine, all of which was ignored. At this pass she again came to me. Her photophobia was so intense that I could not get a glimpse of her pupil, as she kept her eye so well rolled up when the lid was raised that only the lower edge of the iris was visible. The ocular conjunctiva was normal on the right side, or even a little pale, and a very little reddened on the left, the latter being the more sensitive to light and the more guarded by her. I could find no typical uric acid crystals, but found some of characteristic hue, globular in form, many with a stem attached, like a dumb-bell with one bell off. She had grown noticeably thinner, but the belly was still large. Her stools were inadequate, and she had a marked antipathy to oranges. I again ordered the same collyrium, together with the syrup of hydriodic acid (15 minims t.i.d.) and the syrup of the iodide of iron (gtt. xx. t.i.d.).

On August 4 I saw her again. She had been costive up to the day before, when she had loose stools, and passed many pin worms and "objects looking like small tadpoles." Eyes remain the same. Urine is now loaded with uric acid. Her right ear begins to discharge. A year ago, the aunt reminds me, as her eyes began to improve her mouth became very sore, and she supposed the otorrhea was a good augury. Belly very large. Treatment was continued and I added 2 grains of potassium bromide t.i.d. Her irritability was much less. She had not taken the iron. Eats better, and has a penchant for crackers sprinkled with salt.

On Aug. 11 I saw her again. She had had diarrhea all the week, six to eight stools per day; passed a lot of undigested blackberries, but no more worms despite the use of "worm medicine." I now put her upon one-drop doses of the wine of colchicum root t.i.d. On August 21 she was improved in every way, and nine days later she was perfectly well again. A slight photophobia that still existed was promptly relieved by several two-grain doses of potassium bromide, given to reduce retinal irritability.

In this patient there was no substantial improvement from July 27 to August 11, despite local treatment and attempts at constitutional upbuilding, but in the following ten days, during which she took colchicum, improvement was marked. I consider her diarrhea for a week preceding the use of the colchicum to have been a natural effort to rid herself of the enormous excess of uric acid. I have seen such diarrheas so often that my conviction is positive. It is a misfortune that I cannot prove it by microscopic examination of the feces. Such examinations are not as simple as those of urine, they are unusual, and specimens are not as readily tendered.

Aural rheumatism exists, but to what extent I do not venture to say. I have seen but few cases, and, so far as I can recall, they were all in middle life or beyond. Deficient hearing was probably due to stiffening of the ossicular joints, and perhaps also of the tympanic membrane from thickening. But I do recall that they showed an abundance of uric acid in the urine, and were only benefited after the use of colchicum. Local warmth was also of great benefit.

These are the people who sometimes hear better on a moving train or in a machine shop, presumably because of the effect of the atmospheric vibration in causing greater mobility of the ossicles, as in vibratory treatment, which, by the way, is beneficial in these cases. Some may call these cases gouty. So let it be. Good results from the colchicum treatment, or it with the salicylates, are the same, and that is the crux of the matter clinically. In other words, if in such cases of partial deafness there is also much uric acid in the urine, the probabilities favor a prompt remission of symptoms upon the use of colchicum and the salicylates, both aided by hot air and vibratory massage. It must not be forgotten that a rheumatic sore throat may also obtund hearing by extension to, and closure of, the Eustachian tube.

Rheumatic toothache may strike many readers as a novelty, and perhaps existent only in the imagination of the enthusiast. But I shall cite the first instance that called my attention to this condition. The patient happened to be myself.

It was several years ago, while having bridge work done on my left lower jaw, that I developed a constant ache in the socket of the left upper central incisor. It behaved as all such pains do, being obstinately persistent, with a perverse tendency to get worse at night, and more unbearable each succeeding day. The dentist's attention was called to my initial discomfort and final suffering. The usual remedies proved useless. No cavity could be found. Resort was had to the drill finally with a view to getting at or near the pulp to destroy the nerve if necessary or do whatever else might seem expedient. There was, however, neither pulp chamber nor nerve. The entire tooth was one solid piece. Yet the ache continued. Thinking finally that it might be rheumatic because of my uric-acid tendency and proneness to patellar pains that always readily yielded to colchicum, I took the wine of colchicum in five-drop doses four times a day. The pain was much relieved after taking the second dose, and left me toward evening of the next day. Occasionally that tooth has ached since then, but not long, for I promptly hie myself to the colchicum bottle, and the pain vanishes after several doses.

I recall, also some ten or twelve years earlier, taking a trip for two or three weeks to some of the larger cities, combining business with pleasure, together with very little physical exertion but much over-eating. A terrible toothache took hold of me on the fifth day and held me captive in agony till my return. I had a tooth extracted to relieve the pain, but to no purpose. A presumptuous but well meaning old man "pow-wowed" it away for a whole afternoon in the face of my incredulous smiling countenance. This might have been a coincidence, but I looked him up hopefully the next day only to find that he had left the city. My pain remained. Fair sized doses of morphine and opium had not appreciably relieved me by day or night, nor did they afterwards. Upon my arrival home, and resorting to daily active outdoor exercise and a less liberal diet, the pain soon disappeared. I now feel quite satisfied that colchicum would soon have relieved me then as it has so often done since.

Again, let me eat well and work little, and it requires but a lunch at bedtime with a single bottle of beer to bring on a toothache even before the lunch is ended. If these moderate dietetic indiscretions are continued, the pain extends to other teeth, the patellæ, and to the joints of the lower extremities. They are not very severe, but enough to take precedence over all other matters, even if of considerable importance. I have had sufficient scientific spirit to experiment often enough with myself in this matter positively to establish the fact that my toothaches were rheumatic, and they always promptly yielded to colchicum.

Since then I have looked for and found similar cases in others. I may add that my urine almost always contains uric acid detritus, seldom crystals or amorphous urates, during attacks of pain, and becomes free of it after the use of colchicum and the easement of pain.

Enteric rheumatism is no myth. Vague abdominal pain has yielded to colchicum and the salicylates in my hands, and so have many diarrheas. The latter I have viewed, and still do, as nature's effort to rid herself, through the enteric mucosa, of poisonous material in the blood. And why may not the peritoneum, which is really the synovial membrane of the belly joint, be subject to the same influences that so often adversely dominate the synovial lining of the knee, ankle, shoulder, or other joints? I have had patients with such diarrhea and freedom from pain, develop characteristic rheumatic pain after checking the enteric flow, and, contrariwise, have observed disappearance of the diarrhea upon the use of colchicum, or this and the salicylates, sometimes even when it was uncheckable by the usual means. It was in this way that my attention was first directed to rheumatic diarrheas. Finding practically uncheckable diarrhea without adequate evident cause, and noting the urine loaded with uric acid, the usual treatment was given with the gratifying result upon the bowel.

I think it safe to lay down the general proposition that all serous membranes and fibrous structures are prone to irritation in rheumatic conditions, giving rise to appropriate symptoms. These may be direct and unmistakable, or reflex, or referred. Thus irritation of the sciatic at its origin is felt along its distribution (referred sensation of pain). Throat inflammation or active congestion may cause cough (reflex symptom). Again, involvement of the dura would cause characteristic headache.

I do not personally know of pleuritic troubles due to rheumatism, and if I have seen any they were not recognized by me as such. The mere fact, however, that such cases have not been observed is no surety that they do not occur. It seems to me very reasonable to assume that a morbid influence that so generally affects fibrous and serous structures is likely to have a predilection for them all, though in varying degree. Selective affinity for certain tissues or organs, or even choice sites, by special influences, are common. Some authors do recognize a rheumatic pleurisy (Strümpell).

In addition to this generalization, I would add the other, that all the eliminative channels are liable to be affected by the rheumatic influence, *i.e.* the urinary and enteric tracts, the skin, and the respiratory mucosa. And these effects are most often noticeable the nearer the mucosa approaches the skin. We even see well marked cases of pneumonia that yield readily to the salicylates rather than to other medication. Is this not significant?

Cardiac rheumatism is well known. Pneumonias that yield to rheumatic treatment have been written about and reported in large number. Surely the materies morbi of this affection may find other parts of the body susceptible to its influence besides those commonly known to be so. Given the rheumatic condition, and it seems to me that its manifestations may be looked for in any tissue of the body, its site of manifestation depending upon local peculiarities or susceptibilities as yet inexplicable.

Uterine Rheumatism.—I have had cases of intrapelvic pain with ovarian and uterine tenderness, both external and internal, that yielded somewhat to anodynes, a little to cimicifuga and pulsatilla, but entirely and promptly to colchicum and sodium salicylate. Could anything be clearer, especially when there is the usual urinary accompaniment, and repeated attacks with the same response to treatment in the same individual?

Relation of Uric Acid Production and Elimination.—Those tissues in which elimination of waste is apt to run behind the production of waste are the most subject to rheumatic influences: for instance, fibrous tissues and joints. Though elimination is active from muscle, the production of waste material is very great. The soreness and stiffness after unusual active exercise are so akin to those of rheumatism that they may very well pass for being substantially one and the same. When "muscular rheumatism" is chronic there is, in all probability, involvement of the connective tissue framework, and when there is greater wasting of the muscle than is accountable for from non use, then the afferent nerves are involved. In chronic rheumatism of the shoulder joint there is often deltoid soreness and atrophy with some paresis, all most likely due to involvement of the circumflex nerves.

The failure of active exercise to produce pain, after it has been regularly indulged in for a sufficient length of time to insure what is athletically known as "condition," is most probably due to elimination having been so developed as to promptly carry off all waste.

Treatment.—In all of these cases it is requisite to maintain free stools, preferably with magnesium sulphate. The wine of colchicum root should be given in sufficient amount to be effective, and what this is depends upon the peculiarity of the individual and the disease. It is well to begin with five drops every four or five hours, to be increased as appears needful. Sodium salicylate or salicylic acid may be added, beginning with five grains every two hours till effective, or the dose should be increased as necessary. The oil of gaultheria may be used instead of the salicylates, or be combined with them. It may initially be given four times a day in ten-drop doses on sugar. Medication should always be pushed till effective. Book dosage is only a guide for initial amounts, after which one should individualize the patient, and be governed by the effect, the medicine being given in increasing doses or diminishing intervals, either till effective or until physiological symptoms are manifest without satisfactory effect upon the disease, for instance tinnitus with the salicylates or diarrhea with the colchicum.

An important factor in the treatment of rheumatic conditions is heat. This is consistent with the views expressed as to the nature of local rheumatism, as heat increases circulation, and this oxidation and elimination. So also do those electric currents do the most good which have a like effect. Likewise are those medicines the most efficient which promote cellular elimination, by which I mean chemical changes in the tissues that break up and get rid of the rheumatic materies morbi in contradistinction to those which merely empty the bowels of accumulated refuse.

Bathing has a like effect in proportion as it increases circulation and quickens elimination, and a reverse effect as it does otherwise. Hence the efficacy of warm baths and the harmfulness of cold water. The same is true of sun heat, which is always grateful to the rheumatic, especially when applied to an affected part.

Medicinally, those agents are the most effective which hasten and increase elimination from the tissues, for instance the alkalies and the iodides, or improve oxidation, as iron and manganese. Others may be said to be specific in their action, as colchicum and the salicylates. In this connection I may add that I distinctly note such action by those drugs, and

can see no logic in attributing all the good effects of the salicylates to their pain-benumbing qualities, as has been claimed.

This hastily written paper is presented in the hope that it may emphasize the importance of some well-established facts of frequent occurrence that are, however, habitually overlooked. Long dissertation and argument, citation of authorities, and the detailed recital of many cases seem to me inexpedient and unnecessary, and, therefore, inadvisable, on which account they have generally been omitted. After all, plain facts may be simply stated, and are easily capable of verification or disproval, especially those which I have presented, by any practitioner of even moderate experience.

I should recapitulate the salient points of this article as follows:

1.—The etiology of excessive uric-acid formation is unknown.

2.—The symptomatology of uric-acid excess is not fully known.

3.—The name "rheumatism" may generally be used synonymously with uric-acid excess.

4.—The absence of uric-acid evidence from the urine is no guarantee that it does not exist in abundance elsewhere in the body, and require elimination.

5.—Uric acid disturbs all the tissues of the body though some much more than others, and is unusually selective of exceptional tissues in some cases, the reason for which is not understood.

6.—Only a single symptom may exist to call attention to even very large quantities of uric acid signifying the eve of a severe affliction if not promptly eliminated.

7.—Many uric-acid conditions are not recognized as such, and are therefore unsuccessfully treated until the real condition is recognized.

8.—Symptoms that are benefited by colchicum or the salicylates are most probably due to uric acid.

9.—Uric acid causes irritative catarrh of the excretory mucosa, and probably most so as it nears the outer skin, thus affecting the bladder and urethra, as well as the enteric tract.

10.—Toothache of uric acid origin should not be overlooked, and is capable of prompt relief without the use of anodynes.

11.—There exists a visceral rheumatism, or pain and abnormal functioning of the viscera from uric-acid disturbances, promptly relievable by colchicum or the salicylates and proper diet, and probably not by any other means.

12.—Uric-acid symptomatology seems to be due to accumulation of uric acid in the tissues because of its formation in excess of the ability of elimination; on this account structures poor in circulation are subject to its influence, as ligaments, bones, or serous membranes; or those in which, though their eliminative power is far greater than that of those just mentioned, the formation of waste products may be too rapid and bountiful to admit of prompt enough removal to prevent accumulation, as muscle.

13.—Wine of colchicum root is a remedy of remarkable efficiency for the relief of uric-acid conditions, acting promptly in most instances.

14.—The salicylates are valuable adjuncts to colchicum in uric-acid conditions.

15.—The bowels should be kept freely open (not diarrheal) with magnesium sulphate, preferably small doses on arising, the amount depending upon the effect, one or two stools per day being desirable.

16.—Medicines should be pushed until effective, or until physiological evidences of their action ensue.

17.—All influences increasing circulation in or about the affected area are beneficial, such as heat, negative galvanism, the static breeze or spark, or warm bathing.

18.—As a rule all those medicinal agents are helpful in uric-acid conditions which hasten elimination or increase oxidation, as the iodides, alkalies, iron, and manganese.

EARLY DIAGNOSIS OF GASTRIC CANCER, WITH REPORT OF A CASE.*

By Louis M Gompertz, M.D.,
New Haven, Conn.
Clinical Instructor in Medicine, Yale University.

Formerly when the medical attendant made the diagnosis cancer of the stomach, it was like pronouncing the death sentence of the patient, as this diagnosis could not be arrived at until the disease was well advanced, and the treatment then was only palliative—endeavoring to prolong the one-sided battle in which death was sure to be the victor.

I hope that I will not be considered too optimistic when I say that owing to the progress in chemistry, bacteriology, and physiology, the diagnosis of cancer of the stomach can many times be made early enough to enable us, through surgical intervention, to prolong, and in some cases to save, the lives of at least a few suffering from this dreaded disease.

It is not the purpose of this paper to discuss the etiology or pathogenesis of cancer, but to present a résumé of some of the work that has been done by such men as Cohnheim, Boas, Ewald, and others, which enables us to make a comparatively early diagnosis long before the appearance of a tumor or characteristic symptoms.

The subjective and objective symptoms, the chemical examination of the gastric secretions, and the microscopical examination of the contents of the fasting stomach, must be taken into consideration in the early diagnosis.

The subjective or objective symptoms in the early stage of this disease are not always clearly diagnostic, and vary in accordance with the location of the carcinoma, which may be situated at the pylorus, the cardia, or the fundus. They may consist of vague dyspeptic disturbances, such as loss of appetite, pressure and fullness after eating, distention, thirst, nausea or vomiting (depending upon the location of the neoplasm), constipation or diarrhea, sometimes pain and at times a total absence of it, leaving no one characteristic symptom.

Vomiting of blood, the so-called "coffee ground" vomit, has been given much importance as a diagnostic sign, but as this occurs late in the disease, and is often present in ulcer, it seems to the writer that it cannot be regarded as of great diagnostic value without corroborative evidence from the chemical and microscopical examination of the stomach contents.

The well-known cachectic appearance of the patient and the accompanying emaciation are important diagnostic signs, but as they generally appear when the disease is so far advanced that even the medical student—yes, and oftentimes the laity—can make the diagnosis, these conditions cannot be regarded as of any great value in the early recognition of carcinoma.

The presence of a tumor, along with the classical symptoms of cancer, is, of course, pathognomonic, but when they appear the disease is extremely far advanced.

*Read by invitation before the Central Valley Medical Association, Middletown, Conn.

Unless taken in conjunction with the chemical and microscopical examination, we have, then, nothing pathognomonic in all these symptoms which enables us to make an early diagnosis.

Before discussing the examination of the stomach contents, the writer wishes to say that formerly the *modus operandi* of stomach examinations was to him about as familiar as the mysteries of the *x*-ray, and for this reason the exact procedure will be given in detail for the benefit of those who have not given special attention to this line of work.

Patients are instructed to present themselves in the morning with an absolutely empty stomach, no food or drink having been taken since the night before, and, in order to test the stomach secretions, a so-called "test breakfast" is given. Several have been proposed, but the simplest and the one generally adopted is the Boas-Ewald test-breakfast, which consists of a piece of bread or roll weighing about 2 ounces and from 8 to 10 ounces of water. This is allowed to remain in the stomach for from three-quarters to one hour, when it is withdrawn by the use of the stomach tube, the gastric contents being siphoned out, the so-called "expression method." The writer has never found it necessary to use an aspirating bulb, although it has many advocates.

Before the introduction of the tube, artificial teeth should be removed.

The technique of introducing the stomach tube is simple. The patient is seated on an ordinary chair, the physician standing behind with his left arm around the patient's neck, to control the head, leaning forward to introduce the tube. After the tube has been dipped into warm water, the patient is instructed to sit in an erect, comfortable position, and the tube is introduced into the mouth and gently pushed to the base of the tongue. As soon as it reaches this point the patient is asked to swallow, and while this is being done the tube is pushed slowly and gently downward and soon enters the stomach, which we know by a feeling of resistance and the marking on the tube. The portion of the tube outside of the mouth is then lowered and the patient is told to exert pressure on the abdominal muscles, the same as is produced in vomiting or defecation, and by this means a sufficient amount of the gastric contents is expelled through the tube into a suitable receptacle held in the physician's hand, and then the tube is quickly withdrawn.

It is very seldom necessary to introduce the fingers into the mouth, as this is disagreeable to the patient and oftentimes interferes with the introduction of the tube.

The fluid withdrawn is then tested with Congo paper, and if free hydrochloric acid is present, the Congo paper is turned blue. It is then examined for a quantitative amount of free and total hydrochloric acid, but I will not weary you with a detailed account of the various chemical tests, which can be found in all the text-books on gastric diseases.

The absence of free hydrochloric acid in the stomach contents has long been considered as an important diagnostic sign and strongly suggestive of carcinoma. Some writers have even regarded it as pathognomonic. However, free hydrochloric acid is absent in gastritis anacida, and in other diseases not related to the stomach and is present in cases of carcinoma growing on a previously existing ulcer the so called ulcus carcinomatosum.

Ewald says that "in the large majority of cases of carcinoma there is no free hydrochloric acid. This is, however, not caused by the mystic influence of the carcinoma on the production of hydrochloric acid, but simply by the accompanying catarrhal inflammation or atrophic condition of the mucous membrane. Should these conditions be absent there will be a copious secretion of hydrochloric acid."

There is, however, in all cases of carcinoma, with the exception above noted, an atrophy of the glands, so that no hydrochloric acid is secreted and the production of the gastric ferments, rennet and pepsin, diminishes with that of the hydrochloric acid.

The frequent chemical examination of the stomach contents is urged, as hydrochloric acid may be absent at one time and present at another; therefore, a single analysis should not be relied upon, as it proves nothing at all.

While it is true that the absence of free hydrochloric acid is noted in atrophic gastritis and sometimes in certain forms of kidney disease, neurasthenia and anemia, still, if taken in conjunction with other symptoms indicative of carcinoma, it is of extreme value as an aid to the diagnosis. If we rely solely on the subjective symptoms without the chemical examination, the diagnosis must certainly be delayed.

We will now consider the microscopical examination of the fasting stomach contents, and I believe that this examination is of more importance than the subjective symptoms, physical examination, or chemical tests. It not only aids us in arriving at an early diagnosis, but enables us, many times, to tell the exact situation of the neoplasm.

As before stated, the growth may be situated at the pylorus, cardia, or fundus, and the microscopical findings differ in accordance with the location of the cancer.

If the cardiac end of the stomach is affected there is difficulty in swallowing, vomiting immediately after eating, and the patient is conscious of a stoppage in the lower part of the esophagus. The obstruction may be determined by the passage of the gastric bougie, a resistance being met at about 40 cm. from the incisor teeth. So in these cases, the diagnosis is usually not difficult.

When the cancer is situated on the smaller curvature and does not affect either the pyloric or cardiac end, the subjective symptoms and the chemical analysis of the stomach contents are the same as in gastritis anacida, there being no stagnation of food and the test breakfast showing an absence or marked decrease of the gastric ferments.

Therefore, a positive and early diagnosis of this condition—carcinoma of the smaller curvature—can be made only by the repeated microscopical finding of pus and blood, providing their origin can be excluded as coming from an acute phlegmonous gastritis or purulent inflammation from other parts, such as the mouth, tonsils, bronchi, etc.

If the cancer is situated at the pyloric end of the stomach, the orifice naturally becomes narrowed and retention of food takes place. Stenosis of the pylorus may, however, be caused by other conditions, thickening of the pyloric muscle due to the cicatrix of an old ulcer, congenital hypertrophy (which is rare), pressure from without, and benign or malignant growths. However, we will discuss only the conditions found in obstruction caused by a malignant growth. If the cancer has its origin on the site of an ulcer, the chemical examination may at first show an increase of hydrochloric acid and microscopically we get sarcinæ. As the growth of the carcinoma continues, the hydrochloric acid and sarcinæ disappear, and there then takes place the formation of lactic acid. Thus the importance of repeated microscopical and chemical examinations is self-evident, as showing the transition from a benign to a malignant growth.

If the cancer is *not* the outcome of a previously

existing ulcer, chemically, there is usually an absence of free hydrochloric acid, and Uffelman's test shows the presence of lactic acid.

Microscopically, we find food remnants such as muscle fibers, starch granules, etc., and there is present the characteristic lactic acid or Oppler-Boas bacilli. These bacilli are unusually long and non-motile bacteria, with end-to-end arrangement, so that they resemble small angles. These bacilli are present only when lactic acid can be discovered chemically, and Cohnheim asserts that with stagnation and their presence we are warranted in making the diagnosis of pyloric carcinoma in 99 per cent. of the cases, the remaining 1 per cent. being gastritis gravis, or a cancer in the neighborhood of the pylorus; but as surgical interference is indicated in either case, these last two conditions need hardly be considered in the differential diagnosis.

Therefore, when the lactic acid bacilli and stagnation are found in the fasting stomach, and free hydrochloric acid is absent after a test breakfast, no time should be lost in referring the patient to the surgeon for operative treatment. The following case illustrates this:

June 27, 1905, Mr. C. H., age forty-four years, consulted me for stomach trouble which had existed for about one year. He complained of pain, especially after hard food, coming in one-half to one hour after eating; loss of appetite, frequent eructations, which he described as sour in character, appetite poor. Vomiting was not present. The bowels were constipated, alternating with diarrhea. The physical examination showed a fairly well nourished man, tongue slightly coated, heart and lungs normal. No painful pressure points, and in fact nothing abnormal could be discovered at this examination. Weight 126 pounds, which was a loss of about ten pounds in the past year. A diagnosis of gastritis acida was made, the diet was arranged, and medicinal treatment was given. I did not see the patient again for three weeks. There had been no improvement in his condition. A test meal, such as recommended by Riegel, was given in the evening, and the patient was told to present himself in the morning on a fasting stomach. The tube was passed and about 10 c.c. of fluid extracted. Its odor was offensive. Chemically, lactic acid was present, and microscopically Oppler-Boas bacilli and food remnants (meat fibers, starch granules, etc.) were found.

The stomach was then washed out and a Boas-Ewald test breakfast given. Free hydrochloric acid was absent. Total acidity, 4; rennet coagulation, 1/20; pepsin, a little less than 10 per cent.

Diagnosis: Carcinoma of the pylorus.

Immediate operation was advised. This was performed on August 3, 1905, by Dr. L. C. Sanford, at the New Haven Hospital, who reported as follows:

"An incision five inches long was made between the ensiform cartilage and the umbilicus, in the median line. The stomach was readily palpated and a pyloric tumor, about the size of an egg, detected. This was loosely covered by adherent mesentery. There was no general enlargement of the mesenteric glands, although a few glands in the immediate vicinity of the growth seemed affected. These were removed. The tumor of the stomach was isolated and drawn forward into the wound. Clamps were applied on the duodenal end of the tumor and also on the stomach, beyond the tumor. The growth was then excised. The incised end of the stomach was then sutured; the mucous membrane with continuous catgut, the submucosa and peritoneal surface with interrupted silk Lembert sutures. The end of the duodenum was then closed completely in a similar manner. The posterior surface of the stomach and the adjacent surface of the duodenum were incised to admit a Murphy button and the anastomosis was completed. A small omental flap was sutured over the parts anastomosed. The wound was closed completely.

"The patient made an uninterrupted recovery. The temperature was at no time above 99°, the pulse at no time above 90. Small quantities of water were administered by mouth twelve hours after the operation. The patient received saline injections. Soft food in small quantities was allowed on the seventh day. The button passed on the eighteenth day. The patient walked out of the hospital on the twenty-sixth day. Weight, 110 pounds."

The growth was examined by Prof. C. J. Bartlett of the Yale Medical School, who pronounced the tumor to be a Colloid Cancer.

At the present time—over two years after the operation—the patient is well and not suffering from any digestive disturbances. Weight, 146; a gain of 36 pounds.

Twelve hours after a full meal the stomach was empty, showing a regained normal motility. Lactic acid was absent; free hydrochloric acid was also absent. Total acidity, 6; rennet coagulation, 1/20; pepsin, 10 per cent.

The fact that there is no free hydrochloric acid and a decrease of rennet and pepsin shows an atrophy of the gastric glands which took place before the operation. When degeneration of these glands occur they never return.

Examination of the feces after the Schmidt test diet, disclosed nothing abnormal, although repeated microscopical examinations were made. Therefore, the small intestine is apparently performing the digestive function of the stomach.

I wish to emphasize the fact that the diagnosis of this disease can often be made early enough to at least prolong, if not to save, many lives. When there is an absence of free hydrochloric acid, with diminished gastric secretions, after a test breakfast, and the presence of stagnation and the lactic acid bacilli can be determined microscopically, we are justified in instituting operative procedures. While the absence of these bacilli may not exclude the diagnosis of pyloric cancer, their presence constitutes one of the most valuable confirmatory signs, and their detection enables us to make an early diagnosis, while if we wait for pronounced subjective symptoms the case is hopeless.

1195 Chapel Street.

WHAT IS THE FUNCTION OF THE GALL-BLADDER? AND WHY THE FOLDS OF HEISTER IN THE CYSTIC DUCT?

By M. R. BARKER, M.S., M.D.,

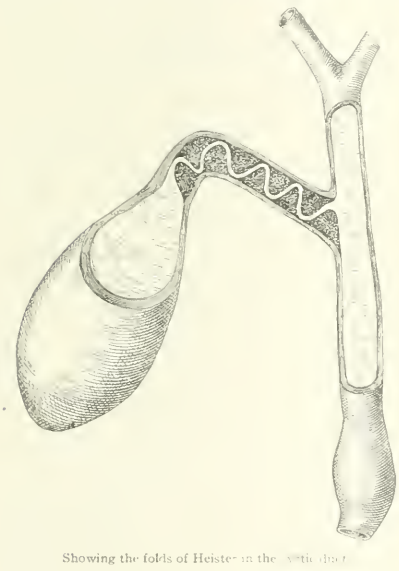
CHICAGO.

That I may answer these queries, and elucidate the subject according to my theories, I must ask the indulgence of the reader while, as briefly as possible, the case is stated and the facts and phenomena upon which it is based related.

I have repeatedly been impressed with what seemed to me to be erroneous teaching in the old and accepted theories concerning this subject, and present my views after careful deliberation, fully realizing that what may seem to me at least approximating truth may to others seem far removed

from it. I shall discuss this subject, then, not with the hope that our theories may prevail, if untrue, but that truth may prevail, as a result of more extended thought and discussion of these questions.

The human system as a complex organism is formed by the uniting together in one structure (the human body) of many systems, each of which works in harmony and for the well-being of all. Each of these different systems, forming this complex organism, is made up of different organs, each of which in turn is especially adapted to the work of the system to which it belongs. Nature has not placed in any of these various systems a useless organ. If by any change in the general system, to meet the ever-changing conditions and environments in which it exists, some organ in any given system becomes useless, it is gradually cast off as a worthless appendage. Every organ, then, in our physical system must be regarded as in some degree useful to the system, and working in harmony with it, until proved to the contrary by the evident decline manifest in it and the gradual elimination of it from the system.



Showing the folds of Heister in the cystic duct.

The gall-bladder has existed as long as humankind have lived, no evidences of decline are conspicuous in it, neither are there evidences that it is being cast off as a useless appendage; hence it must be accorded a useful function in the system to which it belongs. The gall-bladder has been considered as a reservoir for bile, and this theory is widely accepted as true, even at the present time. But is it true? If true, would the gall-bladder be a useful organ in our economy? The gall-bladder holds an ounce, from thirty to sixty ounces of bile are secreted by the human liver daily. How long would this reservoir of an ounce supply a system, the demands of which are from thirty to sixty ounces daily? This old theory makes of the gall-bladder a menace to the system, of which it is a part, and to the general system, by providing a place in which bile may become stagnant, one of the essential factors in the formation of gallstones. Such a function of the gall-bladder is not in harmony with the system of which it is a part, nor of the general system, hence is not true.

The folds of Heister were described by the man whose name they bear, but no function was ever ascribed to them until in a paper, written by the present author two years ago. These folds have ever existed; there are no marks of failure or decline in them; they are a living, active part of our anatomy, to which it is far more reasonable to ascribe a function than to regard them as functionless. No other duct or organ in the human body is provided with such a mechanism. Do they have a function, or are they of that mysterious array of things that just happened, and because they happened once they have been happening ever since, every time a human being is born?

As is well known, the mucous membrane of the cystic duct is arranged in folds along its entire course. There are from eight to ten of these folds. Their arrangement is such that a ridge of mucous membrane on one side of the duct fits a valley on the opposite side, and these alternate throughout the length of the duct. (See the illustration.) If these folds were applied closely it would be impossible for anything to pass through the cystic duct. These folds, or valves, are known as the folds of Heister. No function has ever been ascribed to them except as above stated.

My theories regarding the function of these folds and the gall-bladder are as follows: The gall-bladder secretes a substance essential to the highest physical development and perfect working of the system, but not a substance essential to the life of the system, nor without which the system may not sustain a high degree of perfection and well-being. This secretion is mixed with bile in the gall-bladder periodically, and forced from the gall-bladder into the common duct at intervals.

The folds of Heister are controlled by the sympathetic nervous system, and are always closed tightly, thus preventing anything passing through the cystic duct, except as these folds are relaxed and the duct opened by the nervous mechanism controlling it. The action of this mechanism may be suspended temporarily by anesthesia or surgical procedures, and suspended or completely destroyed by diseased conditions. Or it may act in a sluggish and imperfect manner, in certain temperaments and under unfavorable conditions.

The needs of the system for the gall-bladder secretion act as a stimulus upon the nerve centers controlling the folds of Heister, causing them to relax, thus allowing bile to flow through the cystic duct into the gall-bladder, and there mix with its secretion, diluting it, and rendering its passage through the cystic duct into the common duct comparatively easy, this being necessary because of the feeble contractile power of the gall-bladder and the viscid nature of its secretion. When this cycle is completed the folds of Heister close and remain closed until the system again demands the secretion of the gall-bladder, when the cycle is repeated. Thus this mechanism functionates during the life of the individual, or until disturbed or destroyed by some abnormality.

Having thus briefly stated my theories, what is there to substantiate them? I do not ascribe to the sympathetic nervous system a new kind of function by thus placing it in control of the cystic duct and gall-bladder. Its control of the circulation, the peristaltic action of the intestines, the contraction and relaxation of sphincters, etc., is of the same nature, and is too well understood to admit of discussion. My theory places the biliary passages, including the gall-bladder, in the control of the same nervous system that controls the action of all the viscera of

the abdominal and pelvic cavities. Neither do I utter a new thought in proclaiming the action of the sympathetic upon the folds of Heister to be inaugurated by a nerve stimulus, which stimulus is a need of the system, for every action of the sympathetic is thus inaugurated.

It is a well-known fact, so well known that even the laity are familiar with it, that a certain class of individuals are far more liable to biliary calculi than others are. This class are of the phlegmatic temperament, which is characterized by (to quote from Appleton's Medical Dictionary) flabby muscles, want of energy in the involuntary muscles, turgescence of the tissues, small or slow reaction to psychic excitation, slightly developed passions, and little sensibility to bodily suffering. Another well-established fact is that biliary calculi never form except in stagnant bile. The above facts tend to prove the theory in this way. The folds of Heister and the gall-bladder in this class of cases are controlled by a nervous mechanism that is inadequate, feeble, and only partially responsive; hence these folds are for long periods of time only partially closed in many of these cases, allowing free access of bile through the cystic duct to the gall-bladder, thus rendering the gall-bladder a receptacle for stagnant bile, the most potent factor in the formation of gallstones. Hence we have in this class of individuals the conditions most favorable for the formation of biliary calculi, according to our theory, and the class in which gallstones are preeminently most frequent.

Courvoisier propounded a law, or first called attention to a law that holds good in 75 per cent. of cases. Surgeons who have had much experience with gall-bladder cases are familiar with this law and have verified its truth many times. The law in substance is as follows: When the common duct is obstructed by a gallstone, no diseased condition of the duct being present, the gall-bladder is empty and cannot be palpated. But when the common duct is obstructed by a tumor outside the duct, as for instance carcinoma of the head of the pancreas, the gall-bladder is full and tense, and can be palpated as a swelling beneath the liver. According to the old and widely prevailing theory that the gall-bladder is a reservoir for bile, we should, when the common duct is occluded from any cause, find the gall-bladder full of bile.

If we accept the theory that the gall-bladder is a mechanism for relieving tension in the biliary passages, we must discard the law of Courvoisier; for, according to his law, when the biliary passages are subjected to the greatest tension by reason of obstruction of the common duct by a gallstone, the gall-bladder is empty. We must also discard the folds of Heister as useless appendages, if this theory is true, because of the fact that there are eight or ten of these valves that guard the cystic duct, while the outlet of the common duct is guarded by a single valve in the papilla. Surely the folds of Heister must be useless if ten of them yield to tension before the single one in the papilla yields. But does this occur? Is it not a reasonable conclusion that the single valve in the papilla will yield to tension long before sufficient force could be accumulated to open the eight or ten valves in the cystic duct? And is it not a reasonable conclusion that nature has thus strongly protected the inlet to the gall-bladder and only slightly obstructed the outlet to the biliary passages for the purpose of preventing so far as possible the entrance of bile into the gall-bladder, except as controlled by some efficient mechanism? Courvoisier did not give a reason for the law he propounded; so far as we know, he only announced the law. With the theory as to the action of the folds of Heister, the reason for Courvoisier's law is apparent. When there is an obstruction of the common duct by a biliary calculus uncomplicated by a diseased condition in the duct, the normal action of the folds of Heister is not disturbed, and the cystic duct remains closed, excepting as it is opened at intervals for bile to mix with the viscid secretion of the gall-bladder; after this the diluted secretion is ejected into the common duct and the cystic duct is closed, the gall-bladder never becoming distended. But when the common duct is obstructed by a tumor outside the duct, for instance, carcinoma of the head of the pancreas, the diseased condition has involved either the folds of Heister or the nervous mechanism that controls them, or both, and their normal action is suspended or destroyed; then the cystic duct is open all the time and the gall-bladder becomes distended with bile and its own secretion, and is palpable as a swelling beneath the liver. I submit the above as a logical reason for Courvoisier's law.

When we do a drainage operation upon the gall-bladder and drag its fundus into the abdominal wound, and fasten it there, and then open its fundus and insert a drainage tube, through which to drain the biliary passages, what happens? The cystic duct is dragged upon and abnormally placed, and by reason of this the already enfeebled nervous mechanism controlling the folds of Heister is still further interfered with, and for a time these folds do not functionate at all, and the cystic duct is open, and bile flows through it and out through the drainage tube. The cystic duct is the channel of least resistance to the flow of bile, the common duct always being obstructed by the valve in the papilla; but, as just stated, in these cases the folds of Heister are still more disturbed by the operation and the displacement of the cystic duct. Only temporarily so, however. The stimulation of these folds and of the gall-bladder produced by the operation, clearing them of their débris, and the stimulating effect of fresh bile running through them, restore their action in from two to four weeks, when they resume their normal function, and the flow of bile ceases through the cystic duct and the opening in the gall-bladder closes.

We may put this in another way. It is a well-known fact that the opening made in the gall-bladder for the purpose of drainage will not close as long as bile is flowing constantly through it. If the common duct is closed at the papilla by a valve, and the cystic duct is not guarded by valves or any other mechanism, as has always been supposed, but is simply an open tube, why should the bile ever stop flowing through the cystic duct and through the opening of the gall-bladder when a drainage operation has been done? The conclusion is irresistible that it never would. But the facts are, in the great majority of cases the bile does stop flowing through the cystic duct and through the opening in the gall-bladder in a few days. Why? Because the duct is not a plain tube unprovided a tube provided by an efficient ner needs of the syste resumes its function as quickl these organs overcome the effects of the operation and have time to respond to its beneficial efforts.

If the above is not true, how can we account for the almost universal permanent cures in these cases following operation? If the gall-bladder becomes a receptacle for stagnant bile after the operation, as it was before, would we not have a return of the condition in a great majority of operated cases?

The microscopical examination of gallstones has in quite a large percentage of stones examined resulted in finding the bacillus of typhoid, the nucleus of the stone. So often has this occurred that it is believed that persons who have had typhoid fever are quite liable to the formation of gallstones, and that typhoid fever is one of the etiological factors in gallstone formation. According to my theory, this is a reasonable conclusion. There is no other disease that would be more likely to paralyze the nervous mechanism controlling the folds of Heister, and cause the suspension of their action temporarily, than typhoid fever. Its long debilitating course, its toxic and paralyzing effects upon the sympathetic nervous system, characterized by sluggish action of all the abdominal viscera, would leave little doubt of the suspended action of the folds of Heister during a part of the duration of this disease. Peyer's patches are swarming with the bacillus of typhoid during this disease, and many of them may readily enter the portal circulation, from which they are conveyed to the biliary passages, and, the folds of Heister being open, are carried into the gall-bladder and there become the nucleus of gallstones which may form during the disease or later.

I have stated that the bile flows into the gall-bladder at intervals, and is ejected from it after being mixed with its secretion periodically. Is there any evidence that tends to prove this statement? In forty drainage operations done by me, which I have carefully watched and studied, I have found the following characteristics regarding the flow of bile through the drainage tube more or less prominently marked in every case but two. Immediately after the operation, and for several days, the bile flows constantly through the drainage opening. In about a week the flow begins to assume more of an intermittent character, and usually at the end of the second week, or from ten to fourteen days from the time of the operation, the flow takes place at intervals, sometimes three and four hours apart. The flow now is more in the form of gushes of only a few moments' duration, and only an ounce or two of bile escapes at each gush.

From these facts I have concluded that, as the nervous mechanism controlling the folds of Heister assumes its normal action after being suspended by the diseased condition and operation, the cystic duct is opened by the relaxing of these folds periodically, and the bile flows into the gall-bladder periodically and is ejected from the gall-bladder a short time after, or while the folds of Heister are still relaxed and the cystic duct is open. I believe this is true, because we know the contractile power of the normal gall-bladder is feeble by reason of the limited amount of muscular tissue in its walls; much too feeble to force the folds of Heister when closed.

The relaxing of the folds of Heister; the flowing of bile through the open cystic duct into the gall-bladder; the mixing of the gall-bladder secretion with bile and its expulsion from the gall-bladder into [illegible] duct, and the closing again of the folds [illegible] following each other in [illegible] a in this paper a cycle. [illegible] les are repeated when the general syste[illegible] rmal condition and the biliary apparatus undisturbed by diseased conditions has not been, and possibly cannot be determined, though it is a reasonable conclusion that, if these cycles are repeated once in three or four hours, when the object of the cycle is not attained, the secretion of the gall-bladder escaping through the drainage opening instead of entering the system, they will be repeated much less frequently when their mission is accomplished, and the needs of the system are supplied. I believe the above to be true, though as yet I have discovered no evidence that tends to prove it.

I have stated that in all but two of the forty cases operated upon the flow of bile from the drainage opening has become periodical in nature from two to three weeks after the operation. In these two cases biliary fistula resulted. The discharge in these cases never became periodical, but was continuous all the time, and, after waiting two months for these fistulæ to close, without results, cholecystectomy was done, with the removal of as much as possible of the cystic duct, after which the bile was discharged through the common duct into the duodenum normally and the case terminated.

So far as I know the secretion of the gall-bladder is mucus, and, so far as I am able to judge, about two ounces are secreted by the normal gall-bladder daily. I do not know how this mucus is essential to the best wellbeing of the system, but the fact that it is only mucus does not make it less essential, for if it did not serve a useful purpose Nature would not continue to maintain it.

THE DIAGNOSIS OF GLANDERS IN THE HUMAN SUBJECT FROM THE VIEW-POINT OF A VETERINARIAN.*

By A. SILKMAN, D. V. S.,

NEW YORK.

The writer of these observations has been for a term of years, and is at present employed in the capacity of veterinarian by the Department of Health of the City of New York, and is attached to its Division of Contagious Diseases in the Borough of Manhattan, the scope of his duties embracing the diagnosis of suspected cases of glanders reported by veterinarians in private practice, the confirmation by diagnosis of cases positively reported, and the supervision of measures taken to prevent its spread, viz., disinfection and destruction. He has, therefore, had ample opportunity to become familiarized with glanders in the equine, and, in some instances, in the human subject, and in presenting this, a brief summary of certain of his experiences, for your consideration he is actuated by a sincere desire to promote discussion of this heretofore but little understood subject.

Glanders in the human subject is not by any means the rare disease it is generally supposed to be. I am fully persuaded that many deaths have occurred from glanders which have been incorrectly attributed to other causes, through similarity of symptoms, which have led to erroneous diagnoses.

Glanders may be divided into three forms: acute, subacute, and chronic. In this paper I shall treat of but two, acute and subacute, leaving the chronic form for future discussion in another paper.

In the acute form glanders runs a very rapid course, terminating fatally generally in from twelve to eighteen days after infection. In the subacute form the period of incubation appears longer, and the patient may remain in a condition resembling typhoid for from four to five weeks. In this form the patient may live for six or eight weeks after infection.

It is extremely difficult to diagnose glanders in its first stage. It greatly resembles typhoid fever, and when any suspicion exists the agglutination test

*Read at a meeting of the Veterinary Medicine Association of New York, February 6, 1907.

for glanders should be made, as well as the Widal test, especially in all cases of suspected typhoid where complications are present and where the Widal test has failed of reaction. After a few days lung complications almost invariably occur, which are frequently mistaken for acute lobar pneumonia. A few days later one may get articular pains on motion which resemble rheumatism. Suppurative periarthritis is a not uncommon complication. About this time may be found one or more intermuscular abscesses forming in some part of the body. These abscesses, when opened, will be found to have no true wall or enveloping membrane.

Three or four days before death pustules appear on the face, neck, and shoulders, and frequently all over the body and extremities of the patient, who generally dies before the pustules rupture. These pustules are characterized by rough, uneven ulcerations around the edge of each, and rupture will disclose the contents to be a small amount of yellowish matter. Removal of the tissue covering will discover the true farcy ulceration, a peculiar characteristic of which is that immediately prior or subsequent to death an enemic, whitish areola surrounds it: this, I believe, is a pathognomonic lesion of glanders.

Frequently the lymphatic glands are found to be involved, and often ulcerations occur in the Schneiderian membrane, accompanied by a profuse discharge a day or two prior to death. Orchitis may or may not be present. In the farcy form the glands are rarely affected.

The temperature is of value in the diagnosis of glanders in the human subject. As a rule the temperature is persistently fluctuating, uncertain, and uncontrollable.

Instances exist in which a patient has applied to a physician for treatment a week or ten days after infection. The patient presents a dejected and worn appearance; has an anemic look and a peculiar color. He states he does not feel well, and complains of lassitude, but has no definite idea of what his symptoms are. He gives no hint as to his employment in the vicinity of horses, and the practitioner on examination discovers symptoms of pneumonia and commences treatment accordingly. Or, perhaps, the physician finds an abscess forming and inaugurates treatment for sepsis, recommending the removal of the abscess. An operation discovers a peculiar abscess. This is scraped, washed with a bichloride solution, and dressed with bichloride gauze. Contrary to all expectations, the patient fails rapidly after the operation, and soon dies, the death being variously attributed to typhoid fever, typhoid pneumonia, lobar pneumonia, erysipelas, multiple abscess, or septicemia, etc.

It can be readily understood that the patient, although affected with glanders, has been treated according to the symptoms evidenced when he first presented himself for observation to the practitioner, who makes the return of death in accordance with his original diagnosis.

I have secured permission from Dr. Van Ingen, formerly House Physician of the Presbyterian Hospital, to read his exceptionally well written paper on a case, one of the first in which I was called on for observation. This will serve to illustrate a case of glanders in a human subject from the initial to final stages, exclusive of the autopsy.

Case I.—James C., aged twenty-eight, who gave his occupation as a cook, was admitted to the medical wards of the Presbyterian Hospital June 25, 1903. His family history was negative. He lived in Westchester County, New York, a district where malaria is rife, but which is otherwise healthful. His drinking water was obtained from a deep well. There had been no cases of "fever" in the vicinity. His habits were fairly good. Ten years ago he had his first attack of malaria, since which time there had been a return of "chills and fever" nearly every year of only slight severity. His last attack he thought was about four weeks ago. It lasted only a few days after beginning treatment with quinine.

Two weeks before admission to the hospital he began to suffer from malaise and apathy, which gradually increased in intensity. One week before admission he felt so miserable that he called in a physician, who found his temperature 104.5° F. During the week before he came under our observation his temperature is said to have continued between 102° and 103° F. He complained of a general feeling of soreness, and coughed a good deal, the sputa being mucopurulent, never rusty or blood-streaked. There had been no chills, no epistaxis, no vomiting. The bowels were regular. As there were abundant subcrepitant and sibilant rales over both lungs, with high fever and great prostration, he was thought to have bronchopneumonia. During the last three or four nights before admission he was delirious.

When admitted to the wards with a temperature of 105 F., pulse 112, respiration 30, he appeared to be a fairly well nourished man, prostrated, and apathetic. He looked very ill. The tongue was moist and coated with whitish fur, especially over the back part. Along its margin were four or five yellowish areas from one-fourth to one-half inch in diameter, covered with a yellowish membrane which was quite firmly adherent. At the left angle of the mouth was a similar yellowish area. These patches were slightly elevated, and there seemed to be no loss of substance. There was a good deal of congestion of the pharynx and tonsils, but no exudate was visible. The superficial lymph nodes were not enlarged. The apex impulse of the heart was in the fifth intercostal space, three and one-half inches to the left of the medium line. The heart was acting irregularly, occasionally intermitting, and a soft systolic murmur could be heard at the apex which was not transmitted. Of the two basal sounds the aortic was the louder. The pulse was rapid, irregular, full and soft, not dicrotic, and the vessel wall was moderately and diffusely thickened. Over both lungs a moderate number of subcrepitant and sibilant râles were heard. There was no appreciable dullness or change in breath sounds. The rounded edge of the spleen could just be felt at the costal arch. Over the right deltoid region was a slightly reddened area apparently due to irritation from a hypodermic injection, which soon disappeared. The right knee was considerably swollen and was held in a position of extension. It was hot, but not reddened, exquisitely tender, and measured at midpatella one-half inch more than the left. There was also considerable tenderness on deep pressure over the lower half of the right femur, but no thickening of the bone could be made out. There was no appreciable tenderness over any other bone, nor was any other joint involved. Scattered over the entire trunk was a diffuse eruption composed of small macules about the size of a pin head, lying deep in the substance of the skin. They disappeared almost completely on pressure, and there was no tendency to form large patches. Subsultus was marked. The physical examination was otherwise negative. The extremities were free from eruption. There was no stiffness or tenderness of the muscles of the neck, nor was there any coryza.

The urine was of a specific gravity of 1020, contained a heavy trace of albumin, a considerable number of hyaline and granular casts, and gave a faint indican reaction. No glucose was present. Examination of the blood on the morning after admission showed 7,900 leucocytes. No malarial plasmodia were found, and the Widal reaction was negative. The leucocytes from this time on never rose above 10,500.

During the three days after admission the temperature ran between 103.5° and 105° F., once falling to 102.7° F. The pulse was less rapid, never being above 100, and varying between 76 and 100. The patient presented more and more of the typhoidal condition. There was low, muttering delirium at night, and by day he was slightly irrational and hard to arouse. The tongue became dry, cracked, and tremulous; the abdomen was a little distended. There was a good deal of paroxysmal cough with slight mucopurulent expectoration, which did not contain tubercle bacilli. The swelling of the right knee became slowly more marked. The joint was now held in a position of semi-flexion; tenderness and heat also increased. The tenderness over the lower half of the right femur continued.

On June 29 (fifth day in hospital) the knee had considerably increased in size, and for the first time there was noticed a good deal of induration of the soft parts, with redness, about the outer and posterior aspect of the joint. An exploring needle was introduced into the joint with aseptic precautions, and about two and one-half ounces of thick, sticky, yellowish pus containing small fibrinous masses was obtained. The yellowish areas on the tongue and at the angle of the mouth had enlarged. The deep macular eruption noticed on admission had steadily faded, and appeared now only as a faint dull discoloration of the skin, over which was a very scanty fine desquamation. The temperature this afternoon reached 106° F.

Operation was advised, but owing to delay in the friends reaching the hospital it was not performed until the following evening. On the morning of the day of operation, June 30, the left wrist was swollen, red, hot, and tender; active and passive motion were intensely painful. There were no signs of lymphangitis. The patient was now transferred to the service of Dr. Hawkes, with whose permission the subsequent history is given. Incision of the knee-joint and wrist was performed by Dr. Hawkes on the evening of June 30, and a considerable amount of sticky, yellowish, thin pus, without odor, and containing large fibrin masses, was evacuated from both joints. The patient did badly after the operation. The temperature remained high for the most part, between 104° and 106° F., once reaching 106.4°, and registering 107.2° just before death. Alcohol sponging had no effect upon the temperature or pulse, which later ranged between 110 and 176.

Two days after operation the patient became semi-comatose. At times he was very delirious, but for the most part he lay in a state of semi-coma, from which he could with difficulty be aroused. The discharge from the wounds was at first thin, yellow, odorless, and rather scanty, but in forty-eight hours it had become more profuse, thick, and foul.

July 4 a deep, boggy swelling was discovered just above the right ankle. It was incised, and a small amount of thin yellowish pus was evacuated. It was not well walled off, but extended for some distance between the muscles of the anterior tibial group. A second abscess, which had appeared over the right malar region, was incised and a small amount of thin yellow pus evacuated. During the afternoon a number of reddened areas, varying in size from one-fourth to three-fourths of an inch in diameter, not well circumscribed, were noticed over the trunk, shoulders, and thighs. They were not elevated, but gave a distinct sensation of deep induration. The original deep macular eruption had entirely disappeared. The patient was now in an intensely septic condition, and comatose. Breathing was labored, rapid, and entirely through the mouth, which had become dry and covered with thick adherent mucus. Crusts had formed at the angles of the mouth and in the nostrils. No ulcers could be seen in the anterior nares.

On July 6 another deep-seated, boggy swelling appeared on the dorsum of the right forearm just above the wrist. This was incised, and a small amount of thin, reddish-yellow pus was found lying diffusely between the deeper muscles. None of these abscesses could be traced to bone. The irregular, reddened, indurated areas had now increased in number. They were slightly elevated. The next morning they presented for the first time the following characteristic appearance: Scattered over the whole body, but most numerous on the face and shoulders, were papules and pustules, from one-eighth to one-quarter of an inch in diameter, and with reddened and inflamed bases. Many of them were surrounded by whitish, firm areolæ from one-half to one inch in diameter. The pustules were of a yellowish color, and some of them were umbilicated.

With the appearance of this eruption the question of infection from glanders was inquired into, and it was found that the patient was not a cook, as he had stated on admission, but a fish dealer. He owned a horse, which he cared for himself, and which was shot by the order of the Health Department one week before the patient was admitted, because it was suffering with glanders. The patient steadily became worse, and died the following day, a picture of the most intense sepsis.

Three cultures were made from the blood during life. Those of June 27 and June 30 were both sterile. The third, taken July 5, gave a characteristic growth on potato and in milk, and morphologically proved to be a pure growth of *Bacillus mallei*.

Three cultures were made from the pus from the joints. The first, from that obtained by aspiration of the joint, is reported as showing a growth of a bacillus of unknown variety; it does not give characteristic appearance of glanders bacillus on potato and does not coagulate milk; probably a contamination. The second, from the pus obtained on incision of the joint, showed a growth of pure white colonies and some yellow colonies, the former proving to be *Staphylococcus pyogenes albus*, the latter sarcinæ. The third was made from the discharge from the joints, on July 6, and showed a very abundant and mixed growth, but no *Bacillus mallei* could be isolated.

Immediately after death a culture was made from the pus of an unbroken pustule which gave a characteristic brownish growth on potato, and rapidly coagulated milk, with formation of a yellowish growth on the surface. Morphologically the bacterium was the characteristic glanders bacillus. A pustule was also excised and sections were made which showed the presence of the *Bacillus mallei* in the substance of the pustule.

Unfortunately, an autopsy was not permitted.

Case II.—Another case of interest also treated at the Presbyterian Hospital is that of James M., an Italian, forty-three years old, who applied on No-

vember 12 for treatment, and who died on November 30, 1906. A few facts only will be stated. This man owned two horses. About six weeks before he was admitted to the hospital one of these horses died and the other became sick. Two or three weeks before he was admitted to the hospital the other horse died. He said that the doctor who had treated his horses said that they died of pneumonia. The writer examined the horses stabled where he had kept his and found two of them suffering from glanders. They were destroyed, with another which was condemned on the mallein test. When this man was admitted to the hospital he said that he had been sick for about six weeks.

The point to bring out in this case is that the Widal test was made at three different times, and each time it was negative. About twenty-four hours before death a specimen of blood was taken for the agglutination test for glanders, which Dr. Collins informed me agglutinated 1-1,000 complete. An autopsy was held by Dr. George A. Tuttle.

An intermuscular abscess was opened in the leg, from which was obtained some matter. Two guinea pigs were injected. One died in about twenty-four hours, showing a slight Strauss reaction, death probably being due to septicemia. The second pig died in about forty-eight hours, giving a good Strauss reaction.

Case III.—This is the case of Mr. W— which came under my personal observation. This man was the owner of two horses, employed to haul an ice wagon. Glanders developed in a stable where these horses were kept. I examined all the horses stabled there, quarantined a number, and held them for mallein test. The owner strenuously objected to his horses being held, claiming that they were unaffected, and that they ate as well as ever. Arguments were advanced in favor of the writer's reasons for testing his animals without convincing the owner. In my absence he signified his intention to a stableman of giving one of his horses a bolus, which he subsequently did. While removing his hand from the horse's mouth he discovered that he had been cut on the back of his thumb. The stableman advised him to bathe the wound with a disinfectant, but Mr. W— declined to do so, stating his disbelief in precautionary measures. Three days later he complained of feeling unwell. The fourth day found him no better. On the fifth day one could see he was very ill; he had a drawn, dejected appearance, and was evidently very weak.

Meanwhile, the quarantined horses had been tested, and a number, found to have been glandered, destroyed, among which were two of Mr. W—'s. On the sixth day the writer was informed that Mr. W— was at home, ill, and that his physician had diagnosed his case as one of typhoid fever. On the eighth day he was removed to a hospital, where he was examined and the disease was diagnosed as typhoid pneumonia. I called at the hospital soon afterward, inquired after the patient, and requested to be informed whether the authorities were in possession of a good history of the case. Reply was made by the doctor in charge of the patient that he was fully aware of what Mr. W— was suffering from, that the history was immaterial, and that, were he affected with glanders, he would have so diagnosed it. I differed, and reported the case to the Department of Health as a suspected case of glanders.

Three days later I again saw Mr. W—, by which time it was a pronounced case of glanders, although the doctor still claimed it was not. The next day the patient died, an autopsy was performed by Dr. G. P. Biggs, and the presence of *Bacillus mallei* was demonstrated. The following is from the notes of the autopsy:

The skin presents a large number of suppurating nodules, varying from 1 to 2 cm. in diameter. They are moderately elevated above the surface, and many of them are surrounded by a whitish anemic zone 1 to 3 cm. in width, which is said to have been hyperemic during life. Even the smallest nodules contain a thick yellowish or yellowish-red pus. Those from which the pus has escaped have a depressed center. The largest skin nodule is in the left temporal region, and is ulcerated in its central part. The nodules are mostly in the anterior and lateral aspects of extremities, trunk, neck, and head, being most abundant on trunk and head. In the left nostril a distinct suppurating nodule 3 mm. in diameter is found, while in the right nostril there are found extensive ulcerations. In the subcutaneous tissues, and not involving the overlying skin, there are also several areas of suppuration 2 to 4 cm. in diameter. The largest is found over anterior aspect of left leg and outer aspect of right leg. Soft tissue about the interior two-thirds of left clavicle is much indurated, and skin covering this region has the whitish appearance noted about many of the skin nodules. Incisions into the indurated tissue show many collections of thick yellowish pus 2 to 8 mm. in diameter. No wound of the skin is found to explain source of infection. There is a small amount of fibrinous exudate over the posterior surface of each lower lobe. The pericardium is normal. The heart is normal in size. The cavities contain a moderate amount of dark fluid blood and post mortem clots of fair size. Valves normal. Small petechia in one aortic cusp. Orifices are of normal size. Muscle normal in color, but presents foci of suppuration. Coronary arteries and aorta normal.

Lungs.—The bronchi contain a moderate amount of frothy fluid and are slightly hyperemic. Bronchial lymph nodes not enlarged. Vessels normal. Thin layer of fibrinous exudate covers the posterior surface of both lower lobes. Both lower lobes are very hyperemic and in their posterior parts consolidated to a depth of 1 to 2 cm. This appearance does not differ greatly from that of hypostatic pneumonia. There is an abscess in left lower lobe 1 to 2 cm. in diameter reaching to the surface. Consolidated parts are very hyperemic and not as firm as in lobar pneumonia. A few small foci of suppuration are found in other parts of lower lobes averaging about 2 mm. in diameter. In upper lobes and middle lobe there are scattered foci of suppuration varying from 2 to 5 mm. in diameter, the number being rather greater in upper than in lower lobes. All suppurating foci are surrounded by zones of consolidation 1 to 3 mm. in thickness. Hemorrhages are abundant in pleura over lower lobes.

The spleen is much enlarged. Soft and dark red in color, weight 9 ounces. No foci of suppuration seen. The kidneys weigh 13 ounces, are slightly enlarged. The capsules are not adherent. Surface smooth. Cortices moderately swollen. Markings indistinct. Valves normal. No nodules or foci of suppuration. The intestines were negative throughout, except for a few areas of hyperemia in ileum.

Spine.—In the dorsal region partly behind and to the left side of the aorta and spine is an area of purulent infiltration and induration of tissue extending along the spine a distance of 8 cm. Spine and aorta proper do not appear to be involved.

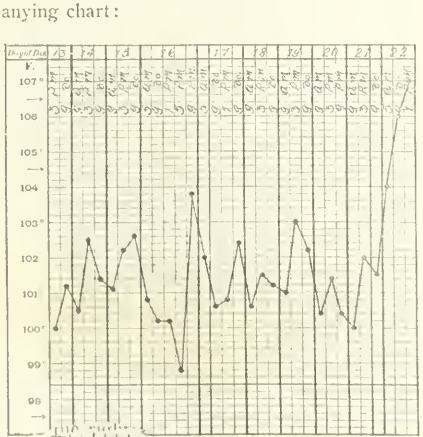
The lymph nodes of body are not found enlarged, and none of them examined contained any pus.

The tonsils and tongue are normal, and the thyroid gland is not distinct. Glanders bacilli obtained.

CASE IV.—On June 13, 1904, Stephen Sanbelia, a Russian, applied at the Gouverneur Hospital for treatment. On examination it was found that he was suffering from cellulitis of the neck. Just above the clavicle on the left side there was some swelling and an area of inflammation. On the arms and legs there were several small abscesses. On June 14 the swelling above the clavicle was examined; it was found that an abscess was forming, and it was thought advisable to perform an operation for the removal of the same. The patient was prepared and removed to the operating room, where gas and ether were administered, and taken well. An incision was made above the clavicle and pus was found. The small abscesses on the arms and legs were opened, and found to contain a pale, yellowish fluid.

After the operation the patient continued to grow worse, and many small abscesses developed upon the arms, legs, and body. There was a little discharge from the nose, which became more and more profuse. This fluid was translucid and adherent, the same characteristic discharge that we see in glanders in the horse. The wound after the operation was dressed with wet dressings of bichloride, but showed no tendency to heal. The symptoms of cellulitis subsided, but those of general sepsis appeared.

The patient was kept on light diet at regular intervals and his appetite seemed to be good; but he failed fast, and on June 22 the Health Department was asked to send some diagnosticians down to see the patient and to determine, if possible, what the man was suffering with. It was my good fortune to visit the patient in company with Dr. S. K. Johnson, who pronounced it a true case of glanders, which was afterwards borne out by the autopsy, and also by the bacteriologist. The patient died at 5:50 P.M. on June 22. It was impossible to get a good previous history of the case. After the patient died it was found that he had worked in a stable where there had been glandered horses. The course of the temperature is shown by the accompanying chart:



The autopsy was held by Dr. Otto Schultz. Skin on the forehead [illegible] one pustule; in the left cheek three pustules, and on the right cheek two pustules, 1 mm. to 1/2 cm. in diameter. The left side of neck is swollen and shows two areas three cm. in diameter, each composed of multiple pustules, and a similar area over the left clavicle of similar diameter. On the right shoulder, arm, and forearm are a number of pustules, some of which are broken through the top, ranging from a few mm. to 1½ cm. On the left forearm there is an intramuscular abscess 5 cm. in diameter. There are a few nodules on belly about 3 mm. in diameter, the same on the thighs and legs. In the right leg is a muscular abscess extending to and involving cutis 4 cm. in diameter. On the neck and over the shoulder blades and dorsal region are numerous pustules, some broken through the top, ranging in size from a few mm. to 1½ cm., the larger ones being prominent about 3 mm. above the surface of the cutis. On the thorax are abscesses as mentioned in the neck. The foci extend through the sternomastoid muscles.

The stomach shows an area of ecchymosis in the most dependant part, near cardia.

The scalp contains a number of pustules, extending down and involving the periosteum, and some 3 cm. in diameter. The inner aspect of the skull shows an intense congestion of the veins, and the same is seen over the dura. There is a flat hemorrhagic membrane over the vertex on the inner aspect of the dura on right side. The vessels of the pia are intensely congested. The velum is also intensely congested. The examination of the brain is negative, outside of intense congestion of all the points. The nasal mucosa is thickened to 3 mm. in the subfossa, and infiltrated with purulent foci. The rest of the mucosa simply shows edema and occasional purulent foci.

In the left lung at the lower margin of upper lobe several foci few mm. in diameter, surrounded by consolidation dark in color.

Bronchi contain a little frothy mucus. The posterior part of the apex of the lung is consolidated, dark in color, not granular; it also contains a cavity measuring about 3½ cm. filled with pus. The lower lobe is congested posteriorly.

The apex of the right lung has a number of slightly yellow-gravish zones, varying in size from a few mm. to 1 cm. in diameter, embracing the surface of the pleura, extending downward into the lung 1½ cm., surrounded by a zone of intense congestion. There are a few nodules in the upper part of the lower lobe.

Heart.—The left auricle contains ordinary postmortem fatty clots. The right is filled with partly clotted, partly fluid dark blood. The heart is normal in size and weight; the valves are normal; the muscle is brown and opaque.

The spleen is enlarged, weight judged to be one pound. The posterior upper part of the spleen embracing a zone 6 cm. in diameter is denser than the rest of tissue, hemorrhagic, flat on section. The liver is increased in size and weight, and judged to weigh about four pounds, intensely congested and opaque on section. The left kidney is slightly enlarged, judged to weigh 6½ oz., cortex swollen, intensely congested, and the lobes gravish white and opaque; the capsule strips readily, the surface is smooth. The right kidney is slightly larger than the left; same condition found.

Larynx.—In the pyriform fossa on the right side is a small yellowish bud 1 mm. in diameter; also one in the left pyriform fossa, and another in the epiglottis, yellowish in color and surrounded by a zone of congestion.

CASE V.—The following case of Mr. S— also came under my observation. This man was a stableman, thirty-nine years of age, employed in a stable

where glanders developed. He complained of feeling ill, and his physician diagnosed the disease as pleurisy. On his removal to the hospital a few days later the diagnosis was changed to pneumonia. About three days prior to his decease a number of pustules appeared on his face, which caused the question of erysipelas to arise. A few moments before the patient's death I managed to procure a small amount of blood with which to try the agglutination test for glanders, which up to this time had not been tried in the human subject. Dr. Collins of the Research Laboratory subsequently informed me that it agglutinated 1-2000 complete. An autopsy was held, and lesions of glanders were found. The duration of illness in this case was eighteen days.

In all cases of glanders in the human subject which have come under my observation connection has in every instance been established between the patient and some horse or horses proven to have been glandered; the only exception was one chronic case. Glanders will not localize at the point of infection. Wounds through which the subject was known to have been infected have healed, before any marked symptoms of glanders have developed, and have subsequently shown no sign of inflammation or infection.

From observations of subacute cases in the human subject, and from experiments with mallein in horses, I am led to believe that with small and repeated injections of specially prepared mallein at the initial stages of subacute cases in the human subject the disease would yield and change into a chronic form, with the possibility of ultimate recovery.

THE INCISION AND TREATMENT OF THE STUMP IN APPENDICECTOMY.*

By JOSEPH B. BISSELL, M.D.,

NEW YORK.

So many different incisions for the operation of appendicectomy have been exploited by surgeons that one would almost be ready to conclude that all are more or less unsatisfactory. A proper opening in the abdominal wall through which to remove the diseased appendix is essential to a good result, and it can be safely asserted that we have such a method of approach. Most surgeons have their favorite incision or choose one at the time of operation, its site, length, and course depending upon the exigencies of the special case in question. A surgeon may make use of a particular form or place of opening in nearly every case, and the profession dignifies it quite properly with his name. Probably every English-speaking practitioner knows exactly what is meant by the McBurney or the Morris operations.

There are numbers of other operative procedures, named after the surgeons who first described or advocated them. A review of the literature of the subject suggests to one the time when every eminent obstetrician had a special forceps called after him. There are usually good surgical reasons why the advocate of each variety prefers his own method over all others, and, accepting these reasons in good faith, a short review of the technique of some of the best known operations would tend to the determination of some route into the peritoneal cavity, combining as nearly as may be all their advantages.

Such a conclusion, if it could be reached, would lead to a much to be desired simplicity in technique, and conserve the best interest of the patient. An ideal form of incision would be one which united all the advantages and avoided all the faults of the best of the various methods in use.

The incision in appendicectomy should be so carried out, while of sufficient size to accomplish its purpose, as to injure as little as possible the structure of the belly wall, the nerves, vessels, fascia, and muscles, and to avoid any tendency to hernia. Many of these operations leave the abdominal wall weakened and give the patient a predisposition to rupture. In certain cases this cannot be prevented, but in no interval operation need it occur. Painful scar and spreading belly wall, necessitating the wearing of a permanent belt, if they follow an interval operation, are also evidences of bad abdominal surgery.

In this case as in every other operation, we should work rapidly. Tait's golden rule was to get into, and out of, the abdominal cavity quickly; a rule which he never broke except to his discomfiture. His phenomenal success before the days of antiseptic surgery was due more to this one factor than to all others, brilliant as his results were. Recovery itself may depend upon speed. Rapid convalescence and clean healing are the sequences of quick operative work. The longer the operation and the more the hemorrhage, the greater the shock, the more profound the depression, and the less the resisting power; hence the increased possibilities of infection.

From a working standpoint the following rules should guide us:

The incision should be so made that (1) the offending organ can be safely, easily, completely, and expeditiously removed; (2) the belly wall itself will receive the least possible damage; (3) the shock may be as slight as a capital operation will permit.

An incision which has the necessary advantages ought also to be one which allows for the possibility of disappointment in our expectations. The finding of pus instead of a simple subsiding or quiescent catarrhal inflammation may make drainage for a longer or shorter time obligatory.

The appendix can be reached anywhere in the right lower quadrant with a liberal incision. It is a safe conclusion that in most cases the long and extensive incisions formerly suggested are not desirable or necessary.

The choice of incision depends upon whether the appendicectomy is one of election or one of necessity, always bearing in mind that in this operation the unexpected not infrequently happens, and that it is well to choose a method, if possible, which will allow for drainage in case suppuration or gangrene is found, even when not anticipated.

Three classes of cases then will influence our decision:

1. The interval operation, so-called, the interval being hypothetical of course, as there can be no interval between two attacks if the second attack cannot take place, the appendix having been in the meantime removed.

2. The late operation; one performed after the formation of an abscess, or when there is present a spreading peritonitis.

3. The immediate operation; when in an acute inflammatory condition the question of operation is most complicated, but is apparently imperative.

In the second case there is no choice. An abscess with well defined adhesions, without regard to other considerations, must be opened widely at the lowest point in the quadrant, where it is most prominent and where drainage is easiest. The operation over the site of the abscess does not make any effort to preserve anatomical structures or to avoid injury to tissues. It is the operation of necessity.

*Read before the Practitioners' Society of East Monmouth County, N. J., June 20, 1907.

If a spreading peritonitis is made out or strongly suspected the median opening offers the best chances. The median operation only is to be used in these cases. It is too far from the appendix to reach and remove it easily, without a longer cut than is advisable. It is used otherwise when the removal of the appendix is incidental to some other operation, as in that for ovarian or other pelvic disease. In the male the abdominal walls are too rigid and thick to permit easy access to the appendix by this route. Its advantages are that no nerves or large vessels are cut, and that by it the abdomen can be rapidly and easily opened and closed.

The Fowler incision is obliquely parallel to Poupart's ligament, the middle of which intersects at right angles a line from the right anterior superior spine to the umbilicus. It divides all the structures to and through the peritoneum; it is 2½ to 3½ inches long; it gives easy access to the appendix but is very liable to be followed by hernia. It is probably the best known and most popular incision.

The French method, introduced by Roux in 1897, is similar with no particular advantage, excepting that the peritoneum is opened in the upper part of the wound at first for diagnosis, the opening being thereafter enlarged if necessary. Sonnenburg's incision is made along Poupart's ligament through all the belly wall structures. It opens close down upon the ileum, often cuts the epigastric artery, and always cuts a large branch of the circumflex and a large vein. It is said to afford the best drainage.

Morris's incision is the shortest (1 to 1½ inches long over the site of the appendix); it is oblique, terminating internally at the edge of the rectus muscle. The muscles and fascia are bluntly dissected; the transversalis fascia and peritoneum are hooked up together and divided by the scissors, which is the only cutting instrument used in the operation after the skin is incised. One catgut suture usually closes the peritoneum, transversalis fascia, and internal oblique aponeurosis. The external oblique with its own aponeurosis is united by means of one or two interrupted sutures. The fat is kept out of the way of the skin sutures, only one or at most three of which are used. This procedure means rapid union, a quick convalescence and a very slight scar, or no scar at all. This incision encounters no vessels of importance and does little or no damage to nerves. It does not provide for unexpected conditions.

McBurney's well-known method needs no description here. It leaves the abdominal wall nearly as strong as before operation, leaves no painful scar, and there is little trouble from cut vessels. It takes a considerable amount of time, and is very unsatisfactory if the conditions necessitate drainage.

Mayo modifies the operation, when drainage is called for, by adding a posterior opening for the drain and closing the wound in the abdomen tightly. This increases the time required, and in most of the cases it is found that the anterior wound becomes infected as well, so that nothing is gained but through-and-through drainage.

The Deaver incision directly through the rectus has the advantage of rapidity. Besides the trauma to the muscle this incision would appear to leave a possible weak point in the belly wall.

Howard Kelly, to whose book on the appendix I am under obligations, prefers to make two incisions when the diagnosis is uncertain. One in the semilunar line to locate the tumor, with the hand in the belly for guidance, then a second incision over the mass or laterally to it, closing the first incision before making the second. Kelly, however, uses the McBurney incision when no pus is present, *i.e.* for most interval cases, and the semilunar incision, to be described next, when an abscess is to be evacuated, and when there is necessity for extensive packing with gauze.

There are numerous other methods of more or less value. Not taking into account any operation which is done primarily with another object, the appendicectomy being merely incidental, as for instance that of Edebohls, who extends the lumbar cut made for a suspension of the kidney, around into relation with the peritoneum in front and opens the cavity to the outer side of the colon.

The semilunar incision has been advocated and adopted with some modifications by several surgeons of ability, and is known also by their names. Originally Krogius of Berlin described, in 1889, a vertical incision, which he called the Schüller incision. This was employed by Sands and Morton and other American surgeons twenty years ago. A modification of this incision was described by Battle in 1895, but had been practised by an American surgeon, Kammerer, before that time, and was advocated by him in the *Annals of Surgery* in 1897. It is a vertical incision about 2½ to 3 inches long, over the right semilunaris. The middle of it is over the appendix, the incision is first through the skin and fat down to the aponeurosis covering the rectus, which is opened the length of the skin incision, but a finger's breadth nearer to the median line. The rectus muscle is retracted toward the left and the posterior sheath and peritoneum are cut through together, avoiding the deep epigrastric vessels which are always seen. The wound when closed is in three layers of sutures not in line with one another. The rectus muscle lies between the posterior lines of sutures and thus secures a firm belly wall. If the adipose tissue of the belly wall is well developed buried sutures bring it comfortably taut. A subcuticular suture closes the wound. All ligatures and sutures are of absorbable material. The drain, if indicated, is placed at the bottom of the wound. Firm union results after its removal.

This incision has the following advantages: Through the wound the appendix is easily accessible. The other pelvic organs can be readily and quickly examined. The incision injures no nerves or vessels. It is of adequate, but not undue length. It admits of proper drainage without interfering with the ultimate result. The danger of hernia is avoided. The operation does not take a perceptibly longer time than any other short operation, hence, there is a minimum amount of shock. Convalescence is short. There is a small linear scar or none at all. It fulfills better than any other operation the rules laid down by Moynihan for abdominal incisions, viz., "To obtain clean and perfect healing and permanent strength in the wound it is necessary to have (*a*) clean, neat incisions; (*b*) an absence of teasing or fraying of the muscle edges; (*c*) protection of the lips of the wound from damage by instruments, hands, or discharges; (*d*) perfect asepsis throughout; (*e*) accurate suturing in layers, sutures of apposition and sutures of support both being used; (*f*) an absence of tension in the wound." All of these requisites are present in this operation. In over 150 cases of the writer, operated upon in the above described manner, some of them dating back to 1898, there had been no hernia.

The treatment of the stump is a most important detail. The proper removal of the appendix is essential to the rapid recovery of the patient. Freedom from pain and from other resulting intraabdominal complications as well as from infective peritonitis depend upon the care with which this is performed.

The procedure has developed a great variety of methods. It would take much less time to name those surgeons of well-known skill who have not developed a particular method of treatment of the appendical stump than to name those who have.

The indications are so simple and the results following the careful carrying out of these indications so certain and satisfactory that it seems a pity that there should be more than one method instead of the thirty or forty in general use. I am speaking, of course, of the typical interval case where there are no, or few, and easily relieved adhesions and where the appendix is not abnormal in shape, size, condition, or position to any very marked extent. Variations can be made in the method about to be described to meet almost any of these contingencies.

The first indication is speed. The second is to do little damage to the tissues about the appendix. The third is to remove or destroy all infectious material. The fourth is to leave behind no foreign body, or material acting as such.

The first is a general rule and is to be applied to the operation as a whole as well as to the detail under consideration. A rapid and certain method of treatment will shorten the time required and thus favorably influence the fate of the patient. Inversion of the stump or the whole of the appendix takes time, and often a good deal of time; it violates the second indication by increasing the necessary trauma to the neighboring tissues.

As has been ably demonstrated repeatedly, the stump is often inverted only into the wall of the cecum, not into its cavity. In this situation it acts like a foreign body and interferes with the local blood and nerve supply, causing symptoms which long afterward may be troublesome and misleading. Persistent pain is one of the results often following this method of treatment. The bad position of the stump constricts and presses upon the anatomical structures so that they easily become a good culture medium for whatever bacteria may be present. I have no doubt that this condition is a most frequent cause of localized infection and fecal fistula. No time should be lost in intricate and tedious sewing of flaps or collars over the amputated stump, neither should an extra series of sutures or ligatures or scarifications be employed. They are unnecessary and take up time. Temporary followed by permanent ligatures have the same objection.

The third indication is certainly not fulfilled if any part of the infected mucous coat is left behind undestroyed. Pure carbolic acid is efficient only to the depth in those tissues to which it readily reaches. In certain cases this may be sufficient. Thorough destruction of all the mucous membrane left behind is the only certain security, and this can be accomplished readily and quickly by the actual cautery.

All non-absorbable suture materials left behind are foreign bodies and act very offensively as such at times. Absorbable sutures act in a like manner until absorption occurs, therefore those sutures and ligatures which remain only just long enough to accomplish the purpose of their insertion are better than those which remain for a longer time than is absolutely necessary. Twenty-four to forty-eight hours is the time usually given for peritoneal adhesions to form fairly firmly. A properly prepared three-day No. 1 catgut is sufficient for ligatures to the stump and the appendix as a rule.

The following method fulfills all the indications as called for above and avoids as nearly as may be, the usual faults in the technique:

The mesoappendix is tied off by one thread of a double ligature passed close to the base by means of an aneurysm needle, and the other thread of this ligature is tied around the appendix close to the cecal wall; a narrow artery forceps grasps the appendix a quarter of an inch away from this last ligature. After surrounding the cecum and protecting the peritoneum in the usual manner with gauze tapes wrung out dry with saline solution, the appendix is burned through rapidly with a red-hot cautery tip, burning out thoroughly the mucous membrane of the stump. The free ends of the ligatures, of which there are two, one for the stump and one for the mesoappendix, are cut off close, unless it is intended to drain. If the wound needs drainage the tips from the ligature around the stump are left long to tie the drain down to later.

The nearest piece of mesentery available is laid across the stump and pedicle. It is not necessary to secure it in place by sutures. If the neighboring serous membrane, mesentery, omentum, or small gut is allowed to fall into place by its own weight, in a few hours, almost before the patient has recovered from the anesthetic, adhesions form and the site of operation is sealed over by nature in the most secure manner. If drainage is to be instituted, a cigarette drain made of a narrow strip of gauze inside a split rubber tube is attached to the base of the appendix by means of the ligature ends which have been left long for this purpose; one of them is threaded into a needle and by this the catgut is carried through one end of the drain, which is tied down to the appendix stump and the free end brought out of the lower part of the wound. The ligature tie is cut off close to the stump and the wound closed in the way described above. At the end of from 48 to 72 hours a little jerk of the drain pulls it off from the disintegrated catgut. The drainage by this time has done its work and the sinus is treated in the usual manner until it fills up. During the operation no washing is done to, nor are solutions used in, the wound or in the abdominal cavity. A very little gentle wiping away of any purulent foci or surfaces is allowed. As little violence as possible is to be done to the peritoneal surfaces. A colleague and myself at St. Vincent's and Bellevue hospitals have treated our appendical stumps after this method for the last seven years, to the complete satisfaction of both patient and surgeon.

A NOTE ON THE SENSIBILITY OF THE HUMAN VISCERAL PERITONEUM.

By EDWIN BEER, M.D.,

NEW YORK

VISITING SURGEON TO SYDENHAM HOSPITAL; ASSISTANT TO BELLEVUE HOSPITAL AND THE MONTEFIORE HOME

A few months ago Drs. Meltzer and Kast presented to the Academy of Medicine of New York City the results of experimental work on the peritoneal sensibility of animals. Their work pointed to the conclusion that the visceral peritoneum was sensitive, and that the observations made under local anesthesia by many surgeons and published by Lennander and others would probably have to be revised.

I am writing this short note at the request of one of the above gentlemen, and shall confine myself to furnishing further evidence of the insensibility of the human visceral peritoneum covering the intestines to touch and to pressure, or to pain as the result of these. I shall not analyze the above-mentioned report, as I have no copy of it at hand, nor is it necessary to call detailed attention to what may have

been sources of error in the experimental work and the deductions drawn therefrom—*e.g.*, the relatively large dose of cocaine used (out of all proportion to the relative amount of nerve tissue), and the fact that what might apply to animals does not necessarily apply to man, and so on.

The observations made in the operating-room under the local cocaine anesthesia are open to the criticism that Drs. Meltzer and Kast have made. The possibility that the visceral peritoneum has been anesthetized could not be denied, though the small doses of cocaine used would make such a general action on the whole visceral peritoneum seem improbable. The proper method of elucidating this point and at the same time meeting this objection, at first blush, seems very remote. Laparotomies under salt-water infiltration would surely be of marked assistance,* though not absolutely conclusive, as simple exposure of the visceral peritoneum might produce anesthesia. Another and more practicable method is one that I have employed. This method avoids the various pitfalls and objections above referred to.

If one makes use of patients with large reducible herniæ containing intestines, herniæ naturally of long duration, one can readily study the sensibility of these parts to touch, pressure, and pain. The herniæ must be large, so that one has a goodly piece of intestine to work with; they must be reducible, so that the visceral peritoneum is in its normal condition and not changed by adhesions. Moreover, they should be reducible so that other loops may be substituted for those usually found in the sac. They must contain intestines, as these are to be experimented on. They must be of long duration, not only to permit of their large size, but to guarantee the secondary changes in the sac (parietal peritoneum), which render this membrane almost free from sensation, as surgeons have so regularly observed at operation.

I have examined nine such large reducible intestinal herniæ of 34 years, 30 years, 25 years, 20 years, 30 years, 8 years, 20 years, etc., duration, and the results of these experiments are in perfect accord with the observations I have made in the operating-room under local anesthesia. Severe pressure on the hernial contents causes practically no pain, either at the time of squeezing or at any time within the next twenty-four hours. Locally the patient may feel a slight sense of pressure, which he regularly refers to the pinching of the skin. There is never any sensation in remoter parts of the abdominal cavity. All my observations up to date bear out the contention of Lennander and others—that the peritoneum covering the intestine is insensible to touch or pressure, or to pain as the result of these. That this pressure is an adequate stimulus is proven very readily by gently introducing the examining finger within the inner ring and squeezing the intra-abdominal parietal peritoneum above and to the outer side of the neck of the sac. Such pressure regularly causes pain of varying intensity, and the pain is referred to the deeper parts. This again is in perfect accord with operating-room experiences, which so regularly demonstrate marked sensitiveness of the neck of the sac as well as the adjacent parietal peritoneum.

*Not long after these lines were written (May, 1907) J. F. Mitchell published reports of two laparotomies under saline anesthesia, and his observations correspond with those made in the operating room under cocaine, *i.e.* the visceral peritoneum is insensitive

CHRONIC PHARYNGITIS.

By R. M. NILES, M.D.,

SCRANTON, PA.

MEMBER OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, LACKAWANNA COUNTY MEDICAL SOCIETY, EX-MEMBER NICHOLSON BOARD OF HEALTH, WYOMING COUNTY MEDICAL SOCIETY, ETC.

Simple chronic pharyngitis generally yields kindly to mild measures, once the nasal chambers are restored to a normal condition. The excessive use of tobacco, particularly cigarettes, the pernicious habit of inhaling the smoke, as well as undue indulgence in distilled liquors, tend to aggravate the condition, and may act as direct etiological factors.

Atrophic pharyngitis, as its name implies, is accompanied by loss of tissue from atrophy with thinning of the mucosa, hyponutrition, and defective secretion.

Simple pharyngitis may be, and often is, accompanied by swelling and hyperplasia. In both there is a disturbance in the normal blood supply, and consequently in the nourishment of the tissues involved. Perverted function is the result.

The treatment should aim to correct errors in hygiene and to prescribe constitutional remedies for existing dyscrasias. The red and yellow iodides of mercury seem, at times, to be beneficial, even in cases presenting no specific history.

Local treatment is of the greatest importance. One must eliminate the etiological factors if possible, or at least mitigate their deleterious effects, and treat the nasal disease which so often coexists with assiduity.

For cleansing purposes I have found nothing superior to my tonsillitis formula:[1]

℞ Pot. bicarb. .....ʒiv
Spt. menth. pip.
Spt. camphoræ.....aaʒss
Aq. ferv. .....q.s. ad ℥iv

This solution readily removes secretion, even when dry and crusted, exerts a mild alkaline and antiseptic action, induces a cool, cleanly sensation, and is unpleasant neither to taste nor smell. All solutions used in the nose should be warm, those in the throat are frequently more beneficial if hot. The strength of the formula given may be diminished, if desired, by the addition of water. The specific gravity of watery solutions, used in the nose, should approximate 1,020. Aqueous solutions may be lowered in Sp. gr. by adding water, or raised by the addition of glycerin or sodium chloride.

After cleansing the nares and pharynx, applications of iodine and glycerin (gr. v-xxx to ℥i), tannic acid and glycerin, resorcin, etc., may be employed. In general I believe the medicaments used are too weak, although in certain cases even very mild applications aggravate the condition. It is wise, therefore, in most cases to begin with the milder applications, gradually increasing their strength as the exigencies of the case demand.

In follicular pharyngitis I am rather fond of strong solutions of silver nitrate applied after cocainizing the pharyngeal mucosa. Strong nitrate solutions cause coagulation of albumin and a superficial destruction of diseased tissue, which is replaced by healthy membrane. The result of its action on the pharynx is similar to that obtained in the uterine cavity by curettage.

As there is an abnormal blood supply with resultant disturbance in nutritive equilibrium, measures which tend to overcome relaxed vascular walls and promote normal tissue metabolism should, and do, prove most advantageous.

[1]Tonsillitis. Medical Record, December, 1905.

Local applications of capsicum[2] act with great celerity in atonic and in ulcerated pharyngitis. In atrophic conditions improvement is naturally slower; however, results are more rapidly and satisfactorily attained, in the majority of cases, than with any other treatment the author has employed. Capsicum acts fully as well upon the pharyngeal mucosa as it does upon the mucous membrane of the nasal cavities.

Vinegar of capsicum (10 per cent. to 20 per cent.) is applied to relaxed conditions. The oleoresin (1 per cent. to 5 per cent.) in cod-liver oil[3] is preferable in atrophic and follicular cases.

Preceding the application of any strong preparation I always cocainize the surface to be treated. One should never use capsicum in a spray, but apply it with a swab, and apply no more than will adhere to the site of application.

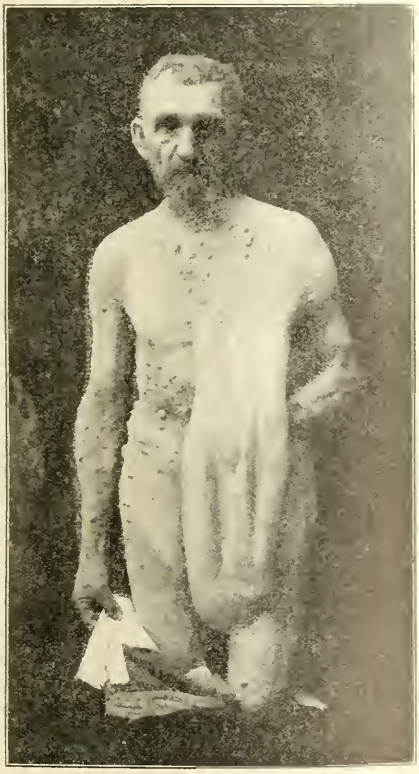
Under the capsicum treatment nodules disappear, atrophic mucosæ become better nourished, passive congestion is relieved, and normal secretion is re-established.

427 Spruce Street.

FIBROMA MOLLUSCUM AND PENDENT TUMOR OF THE BREAST.

By C. WINFIELD PERKINS, M.D.,
PRINCETON, N. J.

Mr. Y., 65 years old, is well nourished and in apparent good health, being capable of a hard day's manual labor. He has a complete indirect inguinal hernia on the left side, but suffers no special inconvenience from it.



The surface of his body anteriorly and posteriorly is covered with fibroid growths varying from the size of a pea to that of a hen's egg. From the left breast hangs an enormous growth, fibroid in character, weighing, as nearly as can be estimated, from 25 to 30 pounds. It is rough and nodular, and at its extremity is bluish in color; no pulsation can be detected in any part of the tumor. The man carries the growth in a bag hanging from the shoulder, and, in spite of its weight and the inconvenience it causes, he absolutely refuses to have it removed by operation.

The growth began about forty years ago, and has been increasing slowly but progressively ever since. The man attributes it to irritation from the strap of his knapsack when he was in the army during the Civil War, as it was first noticed about that time.

Anal Fissure.—The following ointment is strongly recommended and has produced many cures without other treatment: Calomel 4 grains, opium in powder 2 grains, belladonna extract 2 grains, elder flower ointment 1 dram. To be applied frequently. Another ointment for the same purpose is: Lead acetate 10 grains, zinc oxide 10 grains, prepared calamine 20 grains, benzoated lard half an ounce.—*Allingham.*

Abortive Treatment of Suppuration.—A very active means of preventing suppuration has been described by Professor Tillaux, in the *Medical Press.* After the parts are well rubbed with soap and the nail brush, a compress of several folds of gauze, moistened with ether, is placed over the seat of the inflammation, and covered with oil silk, to prevent too rapid evaporation, and fixed by a bandage. The patient is recommended to raise a corner of the dressing every hour to pour in a sufficient quantity of ether to moisten the compress. The treatment should be continued several days. The results are constant, the suppuration retrogrades, and a cure is certain to occur in less than a week.—*Medical Times and Hospital Gazette.*

Uric Acid and Diet.—F. C. Eve calls attention to the work of various prominent investigators in the line of dietetics. He considers that the apparent lack of accord in the relative injuriousness of the varieties of flesh, between analytical anticipations and clinical experience is a serious difficulty, and leads one to suspect that the real nitrogenous culprits, or all of them, have not yet been caught. He thinks that in an ordinary person, on an ordinary mixed diet, only about half of the uric acid and other purins which appear in the urine are due to the necessary wear and tear of the body, the other half being due to purins needlessly taken in in the food. It seems desirable in dieting the large class of patients who appear to have inadequate livers or kidneys to know the amount of purins in the various nitrogenous foods. There is a considerable amount of clinical and experimental evidence tending to prove that purin bodies act as tissue poisons, especially in susceptible individuals, and where the cleavage of the proteid molecule proceeds abnormally. He refers to Haig, who allows only purin-free diet, which is unattractive and mainly vegetable, and to Fletcher and Someren, who insist on a prohibitive duration of mastication, and to Chittenden, who simply limits the quantity of nitrogenous food to its lowest possible limit in healthy individuals. All three of these men have achieved wonderful results, both in health and disease. The writer thinks that a chief result of all these systems is that the quantity of nitrogenous food is diminished by an oblique method which is most useful in dealing with many patients. Another common factor of unknown potency is the subconscious effect of enthusiasm on metabolism.—*The Practitioner.*

WM WOOD & CO., 51 FIFTH AVENUE.

New York, October 5, 1907.

THE DIAGNOSTIC VALUE OF LOCAL TUBERCULIN REACTIONS.

In our Berlin letter dated June 25, 1907, mention was made of the discovery by von Pirquet, physician-in-chief to the Children's Hospital in Vienna, of the diagnostic value of tuberculin vaccinations, and since that time many experimenters in France, Italy, and Germany have tested the method with more or less confirmatory results. The test is simple in its technique and almost entirely without the unpleasant results to the subject which follow an injection of tuberculin. The skin of the thigh or of the arm is scarified as for cowpox vaccination, and on the abraded surface is placed, under antiseptic precautions, a drop of Koch's tuberculin. If the individual is free from tuberculosis, no reaction follows, but if he harbors the germs of the disease in any part a little erythematous patch will appear in from ten to fifteen hours, at the point of inoculation. This is succeeded, at the end of from twenty to thirty hours, by an edematous elevation of a pale pink color, resembling closely an urticarial wheal, and surrounded by an areola of darker hue. Often, about the end of the second day, there appear on this edematous swelling several vesicles the size of a pinhead, filled with a seropurulent fluid containing a great number of multinuclear leucocytes. In some cases there are no vesicles, but merely a pale, lemon-yellow area about the point of inoculation, itself surrounded by a red ring. The inflammatory phenomena gradually fade away, and by the sixth or eighth day there remains only a slight induration, the return to the normal color of the skin being accompanied by a slight desquamation. Von Pirquet regards the test as infallible, at least in young children, but others have not obtained the reaction in all cases of undoubted tuberculosis. Olmer and Terras, for example, obtained a positive reaction in only 20 out of 31 adult cases presenting symptoms of tuberculosis (*La Presse Médicale*, September 18, 1907); they also obtained a reaction in 3 out of 17 cases in which clinical evidences of the disease were lacking.

A modification of this cuti-reaction was suggested by Wolff-Eisner, during a discussion of v. Pirquet's method in the Berlin Medical Society (*Berliner klinische Wochenschrift*, No. 22, 1907); this was the instillation of a 1:100 solution of tuberculin into the conjunctival sac. About the same time Vallée and Calmette adopted a similar procedure—Vallée for cattle and Calmette for man. In order to avoid the irritating action of glycerin on the conjunctiva, Calmette (*La Presse Médicale*, No. 49, 1907) precipitates the tuberculin with 95 per cent. alcohol, and then dissolves it in sterile water. One drop of this solution is instilled into one eye of the person to be tested. Within from three to five hours the individual, if tuberculous, will have a marked congestion of the palpebral conjunctiva, which becomes red and edematous. The lacrymal caruncle is also swollen, red, and covered with a slight fibrinous exudate. The inflammatory reaction continues, and at the end of about six hours the fibrinous secretion has increased so as to form a number of threads in the conjunctival cul-de-sac and at the internal canthus of the eye. The reaction reaches its maximum in from six to ten hours. There is no pain, but the patients complain of a slight burning and of a blurring of vision due to the abundant exudate. All signs of the reaction have disappeared by the end of eighteen to twenty-four hours. In the nontuberculous there is no reaction whatever, or at most a slight redness, which rapidly disappears, and is unaccompanied by lacrymation or a fibrinous exudate. Calmette's first observations (25 in number) were soon followed by those of Latulle, Breton, Painblan, Petit, Comby, Dufour and Bruslé, and others in France, all of which were confirmatory of the value of the method. In Italy, Calzolari (*La Riforma Medica*, July 26, 1907) used the method in thirty-one cases, twelve of undoubted tuberculosis. The ophthalmo-reaction was positive in but three out of the twelve tuberculous persons, but was negative in all of the nineteen nontuberculous. He concluded that the absence of an ophthalmo-reaction did not negative tuberculosis, but its presence afforded positive evidence of the disease. Meille of Turin (*Rassegna di Terapia*, August, 1907) tested for the ophthalmo-reaction in eighteen cases taken at random from among the inmates of the Ospedale Evangelico of Turin. Of ten, who were evidently tuberculous or presented suspicious lesions, all gave a positive ophthalmo-reaction, with the exception of two who had long been under treatment by subcutaneous injections of tuberculin, and had reached a tolerance for large doses (from 3 to 5 milligrams). In all cases in which tuberculosis could be excluded the reaction was negative.

The results of the large number of reported experiences with this ophthalmo-diagnosis of tuberculosis would appear to demonstrate its positive value. It is certainly simple in technique, and it is difficult to see how it can be in any way dangerous if proper antiseptic precautions are observed. It has certain manifest advantages, in that it can be used in dispensary practice as well as in hospital, that the reaction is uninfluenced by the presence or absence of fever, and that it cannot possibly aggravate the general or local phenomena of tuberculosis. It is asserted to be of especial value in the early stages, when our present diagnostic methods are apt to be insufficient, but when it is of the utmost import, as regards treatment, that a positive diagnosis should be made. The method of v. Pirquet is apparently less reliable, as it is often negative in adults who are manifestly tuberculous, while, on the other hand, a positive reaction may, though rarely, occur in those who present no clinical signs of tuberculosis. It is possible that he may have found some method of improving his technique so as to make the cuti-reaction more decisive, for the cable reports that he

declared at the recent Tuberculosis Conference in Vienna that he regarded the method as an infallible means of diagnosis.

BIER'S HYPEREMIA IN ACUTE ARTICULAR RHEUMATISM.

Before Maclagan in 1874 introduced the salicylates in the treatment of acute articular rheumatism, numerous methods were in use, and the fact that they were so many vouched for their uncertainty of cure. No matter what the treatment, mild cases got well in one to two weeks, the majority in three to six weeks, and the severe cases in two to three months. We entered a new era with the use of salicylates, severe attacks and chronic stiffness were no longer so frequent, and yet this drug had its objections. When Bier, therefore, introduced his hyperemia method as a possible cure, it was certainly deserving of trial. In the *Zeitschrift für klinische Medizin*, Volume 64, 1907, E. Steinitz compares the results of one year's hyperemia treatment with one year's salicylate treatment carried out in hospital wards. He used a bandage to produce hyperemia and applied it twice a day for two to three hours, being careful not to apply it so tight as to cause edema, but sufficiently tight to cause redness and increased warmth of the part to be treated. The hyperemia mainly influenced the pain, the latter becoming less marked during the application of the bandage and for a short time after it was removed, this latter period gradually becoming longer. The power of motion was also favorably influenced early, while swelling and temperature were not influenced as early as by salicylates; in other words, the worst symptoms were influenced first. Of 75 patients treated with salicylates, 94.7 per cent. were discharged cured, 39 per cent. before the tenth day, and 65 per cent. before the twentieth day. Of 64 patients treated with hyperemia, 98.5 per cent. were discharged cured, 48 per cent. within ten days, and 80 per cent. within twenty days, but in 16 out of the 64 cases salicylates were also given because the improvement was not rapid enough by the sixth day.

When hyperemia did no good, salicylates usually cured the patient within twenty days, while the opposite was a rare occurrence. With few exceptions the Bier treatment cures pain and in the greater majority of cases as quickly as the salicylates; if relief is not obtained, no harm is done, as the case would probably also have been obstinate to salicylates if they had been used from the beginning, as shown by the fact that patients who did not respond to hyperemia usually took twenty days to be cured with salicylates. Steinitz believes that hyperemia should always be tried first, unless the patient has marked varicosities of the affected limb or objects strenuously to the mode of treatment, or unless the spine, shoulder, or hip joint, where hyperemia is produced with difficulty, is involved. When hyperemia has had little or no effect after five days' treatment, salicylates should be used, either alone or in conjunction with hyperemia; when the latter procedure is adopted, smaller doses of the drug will suffice. High temperature he holds to be no contraindication to the Bier treatment, while a severe kidney or endocardial lesion affords a contraindication to the use of the salicylates.

The Chloroform Habit.

Although the habitual misuse of chloroform for purposes of self-medication must be very rare, instances are not lacking in which this form of drug habit has been resorted to, usually with more or less serious consequences. In most cases the patients have been led to begin the inhalation of small quantities of the anesthetic in consequence of its recommendation for external use by a physician. The results in these cases have involved primarily the nervous system, and a tendency to depression and melancholia, together with other nervous disorders, have been described by several authors. In this, chloroform behaves somewhat similarly to other narcotics, such as morphine and cocaine, and some writers have accordingly recognized a distinct condition induced by the abuse of the drug, and termed by them chloroformism. An instance in which, in addition to the more purely psychical changes, an organic lesion was apparently also induced in this way, is reported by Friedländer (*Deutsche medizinische Wochenschrift*, September 12, 1907). The patient was a middle-aged woman, who for fourteen years had been in the habit of inhaling every night from a handkerchief twenty drops of a mixture of equal parts of chloroform and ether. She had been led to begin this through the fact that this mixture had been prescribed for her by a physician as an external application for rheumatic muscular pain, and had continued to use it regularly by inhalation for its hypnotic and sedative effect. While under the author's care she suffered from several apoplectic seizures, one of which ended fatally, and the discovery of the long-continued chloroform habit was made through the fact that during the stages of excitement attending her last illness even large doses of morphine and other sedatives were without effect, and on the resultant investigation the long-concealed chloroform addiction was brought to light. Inasmuch as none of the usual causes or accompaniments of cerebral hemorrhage existed in this case, and from various theoretical considerations, the author is inclined to regard the persistent and regularly repeated intoxication with the chloroform as the fundamental factor in the production of the localized cerebral endarteritis that was followed by the hemorrhage. It must be admitted, however, that the amount of chloroform taken at each inhalation seems rather small to have given rise to such far-reaching effects.

A New Diagnostic Sign in Typhoid Fever.

Elsewhere we have spoken of the value of a local reaction in the skin and conjunctiva against tuberculin as a diagnostic sign of tuberculosis, but it appears that the principle involved in this process has been found applicable in the diagnosis of typhoid fever, and it may be also in that of other infectious diseases. Chantemesse, in a note in the *Gazette Médicale de Paris* of September 15, 1907, states that he has found the method of service in the case of typhoid fever. He prepared his vaccine material by precipitating the typhoid toxin from a strong solution by means of absolute alcohol. One milligram of the powder so obtained was dissolved in fifty drops of sterile water, and in making the test one drop of this solution was instilled into the inferior conjunctival cul-de-sac of one eye. In healthy persons, or those suffering from some other disease than typhoid fever, a little redness of the conjunctiva with some lacrymation appeared in two or three hours, but disappeared at the end of four

or five hours, and the following day there was no difference to be seen in the conjunctivæ of the two eyes. In typhoid patients, or those convalescent from the disease, the reaction was much more marked. It attained its maximum in from six to twelve hours, and was still apparent the following day. The reaction was characterized by redness of the conjunctiva, lacrymation, and the production of a serofibrinous exudate. The difference in the two eyes was apparent the following day, and could usually still be detected at the end of two, or even three days. Basing his belief upon the results observed in a large number of experiments, Chantemesse ventures the opinion that this method of ophthalmo-diagnosis is devoid of danger and is of definite diagnostic import. Whether it will enable a diagnosis to be made in the very early stages of the disease he is unable to state from observation in the human subject; he obtained, however, a positive reaction in the eye of a rabbit which had received a subcutaneous injection of a typhoid culture only forty-eight hours before, while a similar instillation in the eye of a healthy rabbit was negative. If, as is probable, an ophthalmo-reaction can be elicited in other infectious diseases, and especially if it is positive in the early stages of these affections, we shall be in possession of a method of diagnosis far superior to the diazo-reaction or even to the Widal test—superior by reason both of its certainty and of its simplicity and readiness of application.

The Appendices Epiploicæ.

Riedel was among the first to call attention to the fact that these appendages of the large intestine might play a more important part in surgical pathology than was usually supposed. Even now the number of cases appearing in the literature in which disorders relative to these structures gave rise to conditions requiring operative intervention is comparatively small, but the subject is one that will no doubt gain in importance as the condition becomes better known. An instance in which a fatty appendage of this description with a twisted pedicle was found at operation on an incarcerated hernia is described by Kruger (*Münchener medizinische Wochenschrift,* September 10, 1907), who then discusses the condition in general at some length. Disease of the appendices epiploicæ has so far been observed only in middle or advanced age, and especially in persons suffering from obesity. Through twisting about the longitudinal axis, probably induced through eccentric growth, a pedicle is gradually formed, and degeneration of the distal portion takes place. As the stalk of the appendage grows thinner, and the torsion becomes more pronounced, circulatory disorders result and inflammatory adhesions of the distal portion to the parietal peritoneum, the mesentery, or intestinal loops, may form. The adherent band may give rise to intestinal strangulation, or, if no adhesions form, the distal portion of the appendage may be separated from its stalk and become a free fatty body that may give rise to attacks of pain or peritonitis. These changes may take place in one or more appendices, and the possibility of their occasional presence in femoral or inguinal hernias, especially on the left side, is easy to understand. The appendages are particularly likely to become adherent when they form a portion or the whole of the contents of a hernial sac, and in this way interfere with reduction of the hernia. The pain occasioned by the incarceration of such an appendage in the hernia is usually severe, but general abdominal symptoms are nearly always absent. Hernial complications of this sort are of good prognosis if operated on early, but several deaths have been reported as due to peritonitis originating in strangulation of the appendages.

The Roentgen-rays in Pelvimetry.

At the recent meeting of the British Medical Association some interesting observations were made in the Section on Electro-Therapeutics by J. R. Riddell on the measurement of the pelvic diameters by the *x*-ray. Several difficulties arise in the procedure from the fact that the picture is made by the shadow of the object and because the plane of the pelvic brim and the surface of the plate on which the shadow is cast are not parallel, but lie at a certain angle to each other. Finally, the plate cannot be placed close to the brim nor always at the same distance from it. Various plans of technique were presented. The most accurate is undoubtedly that devised by Contremoulins, consisting in the application of stereoradiography to the pelvic brim. The method is thus described in the *British Medical Journal* of September 14, 1907: "A radiograph is made, the tube being a little to one side of the center of the inlet. A second radiograph is made, the second plate being placed exactly in the same position as the first was, and the tube moved a little to the other side of the center of the inlet. These two radiograms are placed exactly on each other. As each picture is taken by rays emanating from different points, their outlines will not coincide. That taken with the tube to the left will lie to the right of its fellow, and *vice versa.* Round the edge of the shadow of each brim are attached a number of threads; these threads being drawn up, are made to converge and meet at the point from which the rays producing the picture emanated. It is obvious that they will exactly represent the cones of light which produced the pictures, and at the points where the cones intersect an exact reproduction of the object casting the shadows will be made by the threads. The author of the method states that in his hands the whole operation requires less than two hours. Inasmuch as it is impossible to secure that the normal ray falls perpendicularly to the plane of the inlet, this method cannot be said to be absolutely accurate."

Mikulicz's Disease and Syphilis.

The peculiar symptom complex to which this name is given consists in a symmetrical swelling of the lacrymal and salivary glands. Mikulicz himself stipulated that the lesion should be restricted to the substance of the glands themselves without any extension to the surrounding tissues, and also that there should be no coexisting lymphatic enlargements. Other authors, however, have considerably widened these limits and included cases of general lymphomatosis and pseudoleukemia. The pathogeny of the condition is still very obscure, though in some cases tuberculosis has been alleged as the underlying factor. Gutman (*Berliner klinische Wochenschrift,* September 9, 1907) augments the meager statistics of the disease by reporting a case which is particularly interesting through the close connection it appears to exhibit with syphilis. The patient, who presented the typical enlargement of the tear glands and ducts, the submaxillary and parotid glands, had been under treatment four years previously for syphilis, and two months of antiluetic treatment caused the entire subsidence of the various swellings. A year later there were no evidences of recurrence. As syphilis so seldom

affects either of the glands here involved, the rarity of a complex in which both are concerned is easy to understand if this is to be regarded as the etiological agent. In the author's case the relation between cause and effect seems pretty clearly established, and he is probably correct in his contention that this is the first reported instance in which the relationship of syphilis to the disease has been demonstrated.

Picrotoxin as a Preventive of Post-Chloroform Sickness.

In the *Lancet* for September 14, 1907, P. Paterson refers to the use of picrotoxin as a preventive of the vomiting which often follows chloroform or chloroform-ether anesthesia. The author notes the difficulty of determining the true value of any remedy under these circumstances because some patients never vomit at all, but he claims that a comparison of a series of cases in which picrotoxin has been given with a series in which it has not, shows a marked difference. This difference has been especially emphasized in those cases in which, an anesthetic having been given several times, violent vomiting was absent only when the drug named had been administered. It must be given as soon as the anesthetic is withdrawn. The author employs a 0.2 per cent. solution in sterile water and injects 20 minims (adult dose) of this solution into the subcutaneous tissues. For a child of four years 5 minims suffice. If, as rarely happens, sickness appears and lasts ten minutes, a second injection half as large as the first is given. The author is so convinced of the efficacy of picrotoxin under the conditions named that he employs it as a routine measure in all of his chloroform cases.

News of the Week.

Federal Inspection of Dairy Products.—Secretary Wilson is about to ask Congress to authorize the Department of Agriculture to inquire into and supervise the interstate commerce in dairy products, more particularly with a view to preventing the dissemination of tuberculosis and typhoid fever. A private investigation of the conditions existing in the dairy farms in the vicinity of Washington showed a condition of affairs that demanded Federal regulation, and in consequence the new project of the Department was planned.

Beef Eating in Great Britain.—The statistical returns of the British Board of Agriculture show that the amount of meat consumed per capita has practically doubled within a few years, and the proportion of meat to bread in the national dietary has greatly increased.

Yellow Fever in Cuba.—The yellow fever record in Cuba since January 1 is now the worst for several years, seventy-eight cases having been reported up to September 9, with nineteen deaths. All but two of the cases occurred since the middle of May, and during September the number of new cases has increased rapidly. The disease is now present in at least five places.

Advance of the Plague.—More than thirty deaths from bubonic plague have occurred in San Francisco, and the number of verified cases exceeds fifty. The State Board of Health has decided to appropriate $1,500 to be expended in fighting the disease, and steps have been taken to establish a quarantine barge in the bay for the purpose of inspecting and fumigating bay and river craft. Two cases are reported in Marseilles, the patients being passengers on an Italian steamer bringing a number of Syrians from Beirut.

Cholera.—The cholera epidemic in Russia is still spreading, and twelve provinces are now affected. The Volga districts are the most seriously involved, but the disease has also appeared in several places in Siberia.

Roof Garden for St. Luke's Hospital.—Plans have been filed with the Superintendent of Buildings for the addition of a new story to the mansard of the Muhlenberg pavilion of St. Luke's Hospital. The new story is to be used as a roof garden, and its cost is estimated at $20,000.

Expense of Illinois State Institutions.—According to a quarterly statement recently issued, the average per capita cost of inmates of the institutions of Illinois for the quarter ending June 30 was $42.68. The highest per capita was at the St. Charles Boys' School, which amounted to $73.45. The lowest was at the State Hospital for the Incurable Insane, Bartonville, with a per capita of $25.

Mary Putnam Jacobi Fellowship.—The committee in charge of the Mary Putnam Jacobi Fellowship Fund announces that the sum of $8,000 has already been contributed by persons interested in the success of the project. The object of the fund is to furnish aid to post-graduate women students of medicine in commemoration of Dr. Putnam-Jacobi's noble work for women. The Fellowship Fund must amount to at least $25,000, and the Women's Medical Association of New York City invites the hearty and generous cooperation of all who desire to further the higher education of medical women of the United States. The treasurer of the association is Dr. Eleanor Tomes, 136 East Thirtieth street.

Street Car Accidents.—The first report issued by the secretary of the Public Service Commission shows that during the period from August 5 to August 31 the number of street car accidents in Greater New York reached the enormous total of 5,509. The number of persons killed was 42, there were 10 cases of fracture of the skull, 10 amputations of limbs, 44 fractures of limbs, and 83 other cases of injury classified as serious. The Commission requires the traction companies to report all accidents within three days, and if they are at all serious the circumstances are investigated at once.

Medical Training and Character.—The *Lancet* says that as a school of character, it is doubtful if any better could be devised than the routine career of a medical student. It is not claimed that every medical student at the end of his five years' curriculum will be found to have become a saint. But if he has not developed manly qualities of self-restraint, courage, gentleness, and forbearance, it is not for want of opportunity of practising these virtues.

An Epitome of Life.—A physician, writing in a Parisian medical journal, gives the following summary which he offers as a definition of human life: First year, infantile complaints and vaccination; second year, teething, croup, infantile cholera, and convulsions; third year, diphtheria, whooping-cough, and bronchitis; fourth year, scarlatina and meningitis; fifth year, measles. By now half the children are dead. The others live on as follows: Seventh year, mumps; tenth year, typhoid; sixteenth year, chlorosis and spinal irritation; eighteenth year, neurasthenia; twentieth year, cephalalgia, alcoholism, and vertigo; twenty-fifth year, mar-

riage (considered, presumably, as a disease). In the twenty-sixth year, insomnia; thirtieth year, dyspepsia and nervous asthenia; thirty-fifth year, pneumonia; forty-fifth year, lumbago and failing sight; fifty-fifth year, rheumatism and baldness; sixtieth year, amnesia, loss of teeth, hardening of arteries; sixty-fifth year, apoplexy; seventieth year, amblyopia, deafness, general debility, loss of tone in the digestive organs, and gouty rheumatism. For the seventy-fifth year is given death, no doubt a consummation devoutly to be wished by anyone who has passed through this list of vicissitudes.

Small Class at McGill University.—A considerable dropping off is reported in the number of students registering in the first-year class at McGill University. It is supposed that the adoption of the five-years' course and the exaggerated reports in regard to the damage done by the disastrous fire of last spring are responsible for the diminished attendance.

Night School Training Not Sufficient.—The Missouri State Board of Health has decided that medicine cannot be adequately taught in a night school, and has announced that it will refuse to examine for a license to practise graduates of a night school recently established in St. Louis. The college has a charter from the State, and contends that its graduates should stand on the same footing as those receiving their training in schools of the ordinary variety, and will take the matter into the courts.

Bequests to Charities.—Among the bequests under the will of the late General Chas. E. Furlong, the sum of $5,000 is to be left to each of the following: Five Points House of Industry, New York City; Nursery and Child's Hospital, 571 Lexington avenue, New York City; Children's Aid Society; New York Infirmary for Women and Children; Society for the Relief of Destitute and Blind, 219 West Fourteenth street; Asylum for the Relief of Respectable Aged and Indigent Females, 226 East Twentieth street; Babies' Shelter, Day Nursery of Sisters of the Holy Communion, Protestant Episcopal Church, 243 West Twenty-second street. Day Nursery, Sisters of the Good Shepherd, 304 Mulberry street; the New York Foundling Hospital, Sixty-eighth street and Third avenue; New York Infant Asylum, Sixty-first street and Tenth avenue; St. Luke's Home for Indigent Christian Females, East Eighty-ninth street.

International Congress of Hygiene and Demography.—This congress was opened in Berlin on September 23 in the presence of the German Crown Prince and other dignitaries. Prince von Schönaich-Carolath presided, and the Minister of the Interior, Dr. von Bethmann-Hollweg, made a speech, in which he referred to the importance to humanity of the work of the Congress. Dr. Ludwig Holle, Minister of Public Intruction and Medical Affairs, also addressed the congress. Prof. Harrington of Harvard, in behalf of this country, invited the congress to meet next year in Washington. Twenty-three countries were represented by delegates, and the sessions were held for six days. Among the papers read by the American delegates were the following: Dr. Mazyck of Philadelphia on "The Etiology of Tuberculosis;" Dr. Harvey W. Wiley, Chief of the Bureau of Chemistry at Washington, on "Legislation Concerning Foodstuffs;" Dr. Stephen E. Baruch of New York upon "Public and Factory Baths;" Dr. Hermann M. Biggs of New York on "Conquering Tuberculosis and the Care of Consumptives;" Dr. Richard Pearson Strong, Director of the Government Biological Laboratory at Manila, Philippine Islands, on "Preventive Inoculation Against Plague and Cholera;" Col. William C. Gorgas, Chief of the Sanitary Department of the Panama Canal Zone, on his "Campaign Against Yellow Fever," and Dr. Freeman of New York on "Milk Control."

New York and New England Association of Railway Surgeons.—The seventeenth annual meeting of this association will be held at the Academy of Medicine on November 14-15, 1907, under the presidency of Dr. T. H. Dana of Cortland, N. Y. Dr. Robert Dawbarn will deliver the address on surgery on November 14, and on the following day will hold a surgical clinic.

Evanston Medical Society.—At the annual meeting of the Evanston branch of the Chicago Medical Society, Dr. Sarah H. Brayton was elected to the presidency for the coming year. Dr. Ernest L. McEwen was made councillor.

National Association for the Study of Epilepsy.—The eighth annual meeting of this organization will be held at the Jefferson Hotel, Richmond, Va., October 24-25, 1907. Addresses will be given at the first session by the Governor of Virginia, the Mayor of Richmond, and the President of the Medical Association of the State of Virginia. Responses to these addresses will be made by Dr. Everett Flood, president of the association, and by Dr. William P. Spratling of the Craig Colony for Epileptics, Sonyea, N. Y. Reports from all States in this country which are now caring for epileptics will be made by the secretary. All persons interested in the study of epilepsy are invited to attend the meetings of the association. The day following the meeting in Richmond, the association will hold a session at the "Innside Inn" at Jamestown. Persons desiring to join the association should write Dr. James F. Munson, secretary-treasurer, Sonyea, N. Y., or Dr. Wm. F. Drewry, chairman executive committee, State Hospital, Petersburg, Va.

Colorado State Medical Association.—At the meeting of this organization held in Glenwood Springs on September 19, officers as follows were elected: *President*, Dr. H. C. Whitney of Denver; *Vice-Presidents*, Dr. William Marlow of Boulder, Dr. W. H. Swan of Colorado Springs, and Dr. W. W. Cook of Glenwood Springs; *Treasurer*, Dr. E. W. Miel of Denver; *Secretary*, Dr. Melville Black of Denver. Denver was selected as the next meeting place.

North Berkshire (Mass.) Medical Association.—At the annual meeting of this organization held in North Adams on September 17, officers were elected as follows: *President*, Dr. George F. Simpson; *Vice-President*, Dr. H. Bushnell; *Secretary and Treasurer*, Dr. Lyman A. Jones.

Tri-State Medical Society of Illinois, Iowa, and Missouri.—The following were elected officers at the fifteenth annual meeting of this organization held on September 18 in Moberly, Mo.: *President*, Dr. G. O. Cuppidge of Moberly; *Vice-Presidents*, Dr. J. R. Christie, Jr., Quincy, Ill., and Dr. Felix William Garcia, St. Louis; *Secretary*, Dr. J. E. Chambers, St. Louis; *Treasurer*, Dr. Emory Lanphear, St. Louis.

American Society of Sanitary and Moral Prophylaxis.—A regular meeting of this Society will be held at the Academy of Medicine on Thursday, October 10, at 8:30 P.M. The results of the work accomplished by this Society, and the outlook for the future will be the subject of the president's address, and several speakers will consider the various fields of effort of the Society.

The Department of Charities has awarded the

contract for a new ferryboat for the Department, to cost $200,000 and to be completed in two hundred working days. This will be the Department's first new boat in thirty years.

Dr. Harry C. Blankmire of Springfield, Illinois, recently resigned his position as bacteriologist for the State Board of Health.

The Pittsburg Board of Health has been appealed to by the citizens of the Thirteenth Ward of that city in order to secure relief from a plague of large snails which have appeared in great numbers and are causing much annoyance.

Obituary Notes.—Dr. William E. Emery of Surry, Me., died on September 10, at the age of forty-nine years. He was graduated from the Hampden Academy, and received his medical education from Bowdoin Medical College and the Bellevue Hospital Medical School. After practising for a time in Machiasport, he removed to Surry about twenty years ago.

Dr. Gottfried Stamm of St. Paul, Minn., died on September 15 after a long illness. He was born in the canton of Shaffhausen, Switzerland, in 1842, and was educated at the universities of Prague and Berne. He was connected with the University of Zurich for a time, and afterward returned to Shaffhausen, where he practised medicine several years. At the time of his death Dr. Stamm was Swiss consul, having held the position since 1889. His consulate included Minnesota, the Dakotas, and Wyoming. He had been a resident of St. Paul for over thirty-four years.

Dr. Vivian Daniel of Watertown, Mass., died on September 24 in Waltham after an illness of two weeks. He was born in England in 1865, but his family emigrated to Canada and later moved to East Boston. Dr. Daniel was graduated from the Harvard Medical School in 1896, and, after serving as interne in the Boston City Hospital, began practice in Watertown.

Dr. Frederick S. Adams died on September 20 in the J. Hood Wright Hospital of this city, at the age of fifty-five years. His death was the result of a tropical infection contracted during a trip to Guatemala. He was born in Virginia and was graduated from the University of Maryland. He practised for some years, but later devoted himself to chemistry.

Dr. Frederick V. L. Brokaw of St. Louis, Mo., died on September 20, at the age of seventy-three years. He was a native of New Brunswick, N. J., and was educated in Peoria, Ill. He received his medical degree from the St. Louis Medical College, and had practised in that city for over fifty years.

Dr. W. J. Carney of Melrose, Mass., died on September 23 in Hot Springs, Ark., at the age of fifty-four years. He was one of the youngest members of the Grand Army of the Republic, and had practised in Melrose about six years, having formerly resided in Manchester, N. H.

Dr. Panteleon Candidres of Williamsburg died on September 25, at the age of seventy-six years. He was born in Germany, but came to this country while a young man. He was graduated from the College of Physicians and Surgeons in 1872, and, after practising in New York for a time, removed to Brooklyn.

Dr. Rebecca Jane Ayres of Brooklyn died on September 28 after an illness of several months. She was in her fifty-sixth year and had long been a member of the staff of the Memorial Hospital for Women and Children.

Dr. Jas. F. R. Appleby of Washington, D. C., died on September 27, at the age of sixty-seven years. He was a native of Tennessee, had served in the Civil War, and was graduated from Lafayette College in 1864. He received his medical degree from Georgetown University, and had since practised in Washington.

Dr. William Hall Link of Indianapolis died on August 10, at the age of fifty-six years, after a lingering illness. He was graduated from Hanover College, and later became superintendent of Petersburg High School. He received his medical degree from the Medical College of Ohio in 1884, and, after practising in Petersburg for a number of years, he removed to Indianapolis. Dr. Link at one time was a member of the faculty of the Central College of Physicians and Surgeons, and the State College of Physicians and Surgeons, and at the time of his death was clinical professor of obstetrics in the Indiana University School of Medicine. He was a frequent contributor to medical literature, writing mainly on surgical topics.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

COMING SESSION ON EVOLUTION—THEORIES AND HYPOTHESES—AN EDUCATIONAL MEDICAL DEPARTMENT—OFFICIAL RESEARCHES AUTHORIZED—GENIUS AND ALCOHOL—THE LATE TIMOTHY HOLMES.

London, September 13, 1907.

Signs that the long vacation is drawing to a close are multiplying. Prospectuses of the schools have been freely circulated, and the journals have reprinted the pith of these in their so-called "Students'" or "Educational" issues. Many teachers who have been taking a holiday have returned, and those who are to deliver the introductory lectures are preoccupied with preparation for that important duty.

Dr. B. C. Windle, president of Queen's College, Cork, read a paper on Wednesday at the Catholic Truth Congress, at Preston, on "Scientific Facts and Scientific Hypotheses," in which he pointed out that many views, spoken of as theories, never attained a greater dignity than that of working hypotheses, and not a few perished before reaching even that pitch of acceptance. In the biological sciences, he told his audience, hardly any theory could be regarded, even in its measure, as established so firmly as to be comparable to a mathematical proposition. Taking, for example, evolution as a theory. Accepted by most men of science, he said, few of them would assert that it rested on as secure a foundation as a proposition of Euclid, or was a positive fact of science. If so, then this, like others, was only a working hypothesis, though admittedly the most fruitful of results of all hypotheses put forward by scholars belonging to the biological wing of the scientific army. But that was not the view of the compilers of the little manuals which fluttered in swarms from the popular press. It was important to take such manuals at their real value, and not at that set on them by their writers. As a recent writer had said, laymen who wished to follow the trend of modern discovery were limited for the most part to two things—either the pseudo-science of magazines, chiefly arranged for dramatic effect, or specialized technical works, written by the discoverers for their fellow workers—books in which the lay reader became hopelessly lost. Thus the world was divided between men who knew and could not tell, and those who told and could not know.

The real value of a scientific hypothesis was to be estimated by the matured opinion of genuine workers. It was foolish at the first enunciation to accept it as certainly true, or to denounce it. It should be left for a time to the criticism of scientific men, and their criticism could be very corrosive. Of recent years a school had arisen which declared that the slight, almost unnoticeable changes on which the Darwinian theory rested were utterly powerless to bring about any transformation, and that only great mutations could produce a new species. But the hypothesis of natural selection and the efficacy of small variations really lay at the bottom of the whole of the Darwinian edifice. Though supported with all the marvelous skill and all the industry and research of that truly great man, these

views were now controverted, and might possibly find their way to the scrap-heap, where the rusting wrecks of bygone theories have been cast; on which would be found, too, Darwin's beloved "Pangenesis" hypothesis, and perhaps some other of his theories. The matter was well understood by men of science, and the reason why the public had any doubt at all about it was dependence on unreliable manuals and articles, which, for effect, picked up a theory and flaunted in it the face of the public; drawing, moreover, from it deductions which were frequently unwarrantable, and almost always absent from the minds, or at least from the books, of the real originators of the main hypothesis.

This morning it is announced that the Board of Education has decided to establish a Medical Department, to advise and assist in the new duties imposed on it by the recent act in regard to the medical inspection of school children. As a first step, Dr. George Newman has been appointed Chief Medical Officer of the Board. He has been M.O.H. for Finsbury, is lecturer on public health at St. Bartholomew's Hospital, F.R.S.Edin. and D.P.H. Cantab. Dr. A. Eicholz, who has been on the inspectoral staff of the Board doing special work for the deaf, blind, epileptic and defective, will also have an appointment in the new department.

This morning it is also announced that Dr. A. E. Boycott, of the Lister Institute, has been appointed to investigate whether there are any signs of ankylostomiasis in British coal mines.

Another announcement to-day is that the local Government Board has authorized several bacteriological researches on the causes and processes of several diseases. Really, we are getting on!

Sir J. Crichton Browne, who rather likes to have his say on the topics of the day, has been writing in the *Throne* on alcohol. He says that total abstainers, like poets, are born, not made; but constitutionally are composed of very different stuff. He believes they are endowed with a high degree of viability of a low-level type. As a body, they are animated by the highest and most benevolent principles, but are sober-minded and sober-sided, comparatively exempt from the nerve tensions and strains which shorten life, altogether apart from excessive indulgence. By temperament, they probably are less susceptible to various diseases than men of more volatile organization, less likely to expose themselves to excessive wear and tear, and so on, in order to show that the emotional element is unfavorable to longevity. He quotes Madden's tables in support of this, according to which the duration of life of mathematicians is 75 years, of poets 57, moral philosophers 70, dramatists 62. Genius, he concludes, is rarely associated with total abstinence. I expect his critics will want to know how many total abstainers he can count as his intimate friends.

Timothy Holmes is dead. His funeral yesterday was attended by representatives of the profession, and the hospitals, societies, and other institutions with which he had been connected. He had retired for some years, leaving his mark on surgical science and practice, which he taught and practised with success. The five lengthy volumes of the "System of Surgery, Theoretical and Practical, in Treatises by Various Authors," which he edited, look down on me from my library shelves as I write. They are the second edition, which appeared in 1870, and at that date were authoritative as the production of the most eminent surgeons of the time. He himself contributed the articles on burns and scalds, dislocations, aneurysm, excisions, surgical diseases of childhood, surgical diagnosis, and regional surgery. But this great work was by no means all of his contributions to medical literature. He was the author of a "Treatise on Surgery," which was greatly esteemed, and of an elaborate "Treatise on the Surgical Treatment of the Diseases of Infancy and Childhood." He edited an edition of "Gray's Anatomy" and wrote a "Life of Sir Benjamin Brodie," besides papers for journals and societies.

Mr. Holmes graduated at Cambridge, B.A. 1847, M.A. 1850, and was Honorary Fellow of Pembroke College. In 1853 he became F.R.C.S.Eng. Elected on the staff of St. George's Hospital in 1861, he rose through the several offices and retired as Consulting Surgeon in 1887, having long been recognized as one of the most eminent teachers in the school. Later he accepted the office of treasurer to his hospital, and held it for some nine or ten years. He was also Surgeon to the Children's Hospital. At the College of Surgeons he filled the chair of surgery and pathology and the vice-presidency. He had also been president of the Medico Chirurgical Society and vice president of the Pathological Society. Other honors and appointments also fell to his lot.

Mr. Holmes was a medical reformer of the best type, and, by pen and voice, always ready to advocate the cause of justice to his professional brethren. He was a learned surgeon with literary taste, an acute critic and constant contributor to the press. He had somewhat failed in health, but he retained his faculties almost to the last, passing away at the ripe age of 82.

THE INTERNATIONAL CONGRESS OF PSYCHIATRY AND NEUROLOGY.

(From Our Special Correspondent.)

AMSTERDAM, September 7, 1907.

FOLLOWING the opening of the Congress, as described in a former letter, a visit was made by many of the delegates to a museum near by, in one room of which were exhibited a number of instruments of restraint, cages, cribs, and chairs, which were in use in the old-style asylums. This collection was made at the suggestion of Queen Wilhelmina, whose interest in ameliorating the condition of the insane is great.

Delegates to the number of 105 were present from the following countries: The United States of America, Belgium, Brazil, Germany, England, Scotland, Ireland, France, Italy, the Netherlands, Austria, Poland, Japan, Russia, Argentine Confederation, Bulgaria, Chile, Denmark, Spain, Greece, Roumania and Sweden. Several hundred others were listed as auditors, visitors and contributors to the success of the undertaking. As delegates of the Government the United States was represented by Henry G. Beyer of the U. S. Navy, Smith Ely Jelliffe, New York, W. W. Keen, Philadelphia, Carlos F. MacDonald, New York City, William A. White, Washington, and Mary A. Wolfe, Norristown, Pa. Hughes represented the *Alienist and Neurologist*, Jelliffe the American Neurological Association, E. E. Southard the Boston Neurological and Psychiatric Society, Ferris the New York Neurological Society, and Camp the Philadelphia Neurological Society.

At the first general meeting of all the delegates, MacDonald of New York presided, and papers were read by Bechterew of St. Petersburg on "Objective Researches in Psychic Activity," and Gaskell of Cambridge, England, on "The Evolution of the Vertebrate Central Nervous System." At the third of these general meetings, under the presidency of Mott of London, Pick of Prague read a paper on "Senile Brain Atrophy," van Gehuchten of Louvain read a paper on "The Mechanism of Reflex Movements," and MacDonald of New York read a paper on "Development of the Modern Care and Treatment of the Insane as Illustrated by the New York State Hospital System."

At the meetings of the First Section, that of Neurology and Psychiatry, among the papers presented was one by Ramón y Cajal of Madrid, on "Traumatic Degeneration of Axis-Cylinders of the Stag"; by Dupré of Paris on "Differential Diagnosis between General Paresis and other Forms of Acquired Dementia"; by Moreira and Peixoto of Brazil on "The Mental Maladies of Brazil"; by Janet of Paris, Aschaffenburg of Cologne, Jung of Zurich, and Jelgersma of Amsterdam on "New Theories on the Origin of Hysteria"; by Sollier of Brussels on hysteria; by Pick of Prague, Monakow of Zurich, and Liepman of Berlin on "Asymbolia, Apraxia, and Aphasia;" by Oppenheim of Berlin, who demonstrated a brain tumor; Claude of Paris; Ernest Jones of London; Putnam of Buffalo; Mott of London; Sterling of Warsaw, and several others.

Dr. Louise G. Robinovitch of New York illustrated her method and theory of resuscitation of victims supposedly killed by the electric industrial current, she employing a galvanic current for this purpose.

Before the Section on Psychology and Psychophysics, Sollier of Brussels and de Sarlo of Florence discussed the Lange-James theory of the emotions; Marro of Turin read a paper on "The Physiology of Puberty"; Jodd of Vienna discussed the difference between perception and idea, while Bychowsky of Warsaw and van Wayenburg of Amsterdam presented important papers.

The Section on Nursing of the Insane was especially crowded and much valuable material was presented before it also. "The Nursing of the Insane in England" was the topic of the paper of Seymour Tuke of London; "The Reform of Nursing for the Insane in the United States," by Cowles of Boston, was read by Blumer of Providence; and the whole subject of the duties and rights of the nurses was discussed. Morel, Commissioner in Lunacy of Belgium, and van Hamel of Amsterdam debated upon the care of the insane criminal, while Claye Shaw of London read a paper on "The Analysis of the Mental Process in Criminal Acts"; A. Marie of Paris a paper on "Traumatism in Mental Alienation," and an ex-

tended discussion of the theme "Organization of Hospitals for the Insane and State Supervision" was opened by Ruysch of the Hague, and carried forward by Marriera of Barcelona, and others. Methods of boarding out the insane and their open-air employment were discussed by A. Marie of Paris and Meeus of Gheel. A brief but forcible review of the increase of nervous diseases and insanity was presented by William W. Ireland. The education of backward children was discussed by Ferrari of Bologna and Trüper of Jena. A communication was received from Ferrari and Frank, suggesting the inauguration of an international institute for the study of the causes and the prophylaxis of nervous and mental diseases.

The fatigue incidental to the scientific labor of the sections was relieved through the hospitality of the people of the city. On the evening of the opening day of the Congress, a reception was given to the delegates and their ladies at the mansion on the Keizergracht by a committee of eleven ladies of Amsterdam. This mansion is devoted to municipal social functions and has spacious parlors, a ballroom, and an attractive garden. On the following evening there was a reception at the Students' Club, with an entertainment which included clever shadow pictures, pleasantly burlesquing some of the delegates, well-known citizens, royalty, etc. Next came an excursion by steamer to Zaandam, with a visit to the house where Czar Peter the Great resided during his study of Dutch shipbuilding. On one evening the delegates and visitors enjoyed a performance at the Municipal Theater, wherein works of old Dutch masters were presented as living pictures, with a comic operetta representing Dutch rural life, and the rendition of old Holland folk-songs by a large chorus of peasant girls in native costume. Special dinners were spread at the instance of various hostesses and receptions were held by the Burgomaster and Mrs. Van Leeuwen, and by Dr. and Mrs. Tilanus.

To-day the round of gaiety and the strenuous scientific program come to an end. The sections having finished their work yesterday, the time was devoted to an excursion to Leyden, to the Hague, and to Scheveningen, and visits to the hospitals for the insane, Endegeest and Rhijngeest.

JUDICIAL DISPOSAL OF THE INSANE.

To the Editor of the Medical Record:

Sir:—Permit me to say a word regarding a paper read by Dr. R. B. Lamb of Matteawan before the Medical Society of the State of New York (*New York State Journal of Medicine*, August, 1907). The caption of the paper was "The Criminal Lunatic—His Status and Disposition." Members of the medical profession, especially those "who may be qualified examiners in lunacy or lunacy commissions, appointed by the courts" for whose enlightenment he says the information was specially intended, will doubtless feel grateful to Dr. Lamb for furnishing data easily accessible to professional or non-professional men interested in insane statistics. Special attention is directed to the injustice of the system prevailing previous to 1890, before which date the unconvicted insane were associated with the insane criminals in one building. In doing this he uses but thinly veiled the language and arguments employed in the annual report of the State Commissioner in Lunacy of 1889. Though he does not claim originality, so far as this feature of his address is concerned, he appears by implication to stand sponsor for it, as if he had in a certain sense been contributing to the removal of the abuses complained of. This, of course, would be misleading and totally at variance with actual facts.

In the report mentioned (pp. 44, 45, and 46) the commissioner directed special attention to the manifest injustice of associating the unconvicted with insane convicts of our state prisons; that those persons, whom a presumed innocence should protect, were thus associated with convicts in the state asylum at Auburn, especially created for the convict insane. "This association of convicts with the unconvicted seems unfortunate, and in the opinion of the commissioner calls for a remedy. To patients who may recover, it is a source of much mortification to feel that they had been in an institution for the criminal classes, and to the friends of inmates as well it is a humiliation to know that their relatives are detained in an insane asylum for convicts."

"There were present in this asylum for insane criminals at Auburn, September 30, 1888, sixty-seven men and seven women who had never been brought to trial; also eleven men and two women acquitted on the ground of insanity, in all eighty-seven persons." (Report, p. 64.) "The commissioner, therefore, suggests that the law providing for the new asylum for insane criminals at Matteawan be so changed that this asylum shall be called the *Matteawan State Hospital*, and the institution devoted to the care of the dangerous insane, and its management made to conform to that law governing other State institutions for the insane."

Furthermore, the commissioner showed how imperative was the need of a change and recommended a revision of the statute which permitted a commingling of the criminal insane and insane criminals. His proposed reform met with much opposition at first, but it was finally adopted, though not in its entirety. Notwithstanding all that has been accomplished in the removal of abuses, Matteawan still rests under the stigma of receiving all cases of insanity which appear in the county penitentiaries, who are under sentence for petty crimes and misdemeanors, and also those insane under sentence of death, who are committed by the order of the Governor. The institution is still under the management of the prison authorities of the State, instead of being under the same State laws governing other institutions for the insane, as it certainly should be.

In the case Dr. Lamb cites of the man condemned to death and examined by him, with the result that the sentence was commuted to imprisonment for life, the doctor's statement of the incident would lead to the inference that the law regards a person as irresponsible for crimes committed while intoxicated. The reverse of this is the case, for the judicial systems of probably all civilized countries would regard drunkenness (unless in cases of chronic alcoholism) as no palliation of the crime. It would certainly be a singular plea in law as in ethics, which would excuse one offence by the commission of another. Referring to constitutional inferiority the doctor remarks: "The mental responsibility is diminished and always in question. As a class they receive no legal consideration whatever." In rejoinder to this it may be stated that the administration of law and justice would be an impossibility if judges were to assume the functions of psychological moralists, unguided by precedents and unlimited by legal enactments; God alone can determine the degree of moral guilt of any individual charged with a crime. Human society does not punish crime because it is a sin, but for the reason that it is an offence against the social order, and to act as a deterrent in the case of others that may feel criminally disposed. Were the authorities to act upon Dr. Lamb's suggestion, relative to instituting a *de lunatico inquirendo*, in the cases of criminals and misdemeanants, we would acquire as many asylums as prisons; in fact, all or nearly all our prisons might be closed as having survived their usefulness. Adopting his recommendation and accepting his hypothesis as correct, all men guilty of crimes, or of conduct beyond the normal, might be adjudged insane.

Sanity, consistent with legal responsibility, does not imply perfection in any sense, not even in a realization of the distinction between right and wrong. Men who have but an imperfect conception of such a difference may be held equally guilty with those similarly accused, whose moral faculties have been more highly developed. It is sufficient to decide the question of legal responsibility, if the person charged with crime is aware of the character of the act and its consequences.

Relative to laymen deciding upon the sanity or insanity of individuals, Dr. Lamb has this to say: "The present system which permits consideration of lunacy cases by lay jurors proves in actual practice but little short of farcical. . . . Few men of average intelligence would undertake to pass upon a question of internal medicine, such as disease of the heart and lungs. They would show the same hesitancy in passing on mental disease were the privilege allowed them." Doubtless better results would be obtained if men were solely employed in determining such a question, who by profession and training had studied the symptoms of perverted mental and physical functions. But the doctor in attempting to establish a parallelism betwen a lay consideration of physical and mental diseases is illogical. While the physician is fully equipped and trained to detect the evidences of heart or lung trouble, in a majority of cases of mental disease he has but little advantage over the intelligent non-professional man. Mental disease may exist without displaying any symptom whatever of its presence. A postmortem examination of the brain of a lunatic conveys no intimation of the perturbed condition of his mind while living. In cases where professional alienists have been employed to determine the mental condition of persons, their differences of opinion have been often such as to bring them as a class into disrepute, and to destroy to a great extent the confidence of the public in their decisions. That harmonious relationship of man's mental, moral, and physical attributes which would constitute perfect sanity probably does not exist at all. There

are sharps and flats beyond the normal scale, which disturb the harmony of the diapason of consciousness in nearly all lives, and there is a cog loose, something misplaced, in the mental mechanism of the sanest. The line of demarkation differentiating sanity from insanity has never been clearly defined, and it is quite safe to assume never can be so defined. To cite a few famous instances, what could the professional alienist learn of the mental condition of the crazy philosopher, introduced by Dr. Johnson in his delightful story of "Rasselas, Prince of Abyssinia," unless the philosopher was led to speak of his pet delusion? Bishop Butler confessed to being tortured by crazy illusions and fancies, but it is quite certain an inquiry into his sanity would have revealed nothing to the alienist. A critical examination of a religious enthusiast, gone mad, who feels prompted, by what he supposes divine warrant, to commit a crime, would reveal nothing to the most perspicuous student of perverted mental action, if the victim of the insane delusion kept his lips sealed. Many regarded by their fellow men as among the sanest have illusions; it may be of the senses or intellect, or both, but they know them to be merely the results of misdirected function and their illusions do not affect their conduct as well behaved members of the community. The law does not, cannot, scrutinize the secrets of human consciousness, and so long as men's and women's conduct squares itself with the ordinary experience of the race, they are properly regarded as sane and responsible. And even in cases where certain eccentricities and divergencies from the normal are marked, the law does not interfere and should not interfere while those peculiarities do not endanger human life or interfere with the regulated course of human society.

With reference to sane persons charged with crime, attempting to escape the consequences of their acts by pleading insanity, Dr. Lamb has this to say: "I say to you that ten insane persons pass through the courts and are made convicts, where one sane rascal successfully interposes the plea of insanity." He advances no argument and gives no statistics to support his astounding assertion. He makes the simple, uncorroborated statement, and does it, moreover, with an insistence which assumes consent as a foregone conclusion and contradiction as out of the question. What warrant has he for saying this? None whatever, at least none which could influence the judgment of any well-poised mind. Dr. Lamb finds fault with the New York State legal definition of insanity, but suggests no better one. Doubtless a more generalized definition and one wider in its scope might be adopted, but it is questionable if this would advance the cause of justice. As it is the law authorities do not require to be psychologists or physicians to decide upon questions of mental aberrancy within the limits of the simple, legal explanation of the term. Were Dr. Lamb's recommendations to be acted upon it would (as heretofore noted) so greatly embarrass legal proceedings, at all events so far as questions of insanity are concerned, as to make the administration of law well-nigh impossible.

Samuel Wesley Smith, M.D.
7 West Twenty-sixth Street.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 19, 1907.

A Suppurating Supernumerary Ureter Opening Into the Prostatic Urethra.—A case of this very rare anomaly is reported by A. L. Chute. His patient was a man of forty-two years with an old history of urethritis and epididymitis and a recent history of backache, pain over the pubes, in the groins and perineum, and frequent nocturnal micturition. Examination showed the right kidney to be normal. Washing out the left kidney pelvis gave but temporary relief from the turbidity of the urine, which was present, and it was believed that the organ should be thoroughly drained and possibly removed. The patient refused operation and was lost sight of for eight months, when he returned with all his old symptoms in an aggravated form and additional symptoms suggesting sepsis. Later operation revealed a normal ureter on the left side, while behind the bladder to the inside of the normal ureter and very closely bound to it by adhesions at the point where the normal ureter joined the bladder there was a thick-walled tube which appeared like a bit of small intestine without any peritoneal coat. This tube ran along on the bladder, then rose, becoming much convoluted, out of the pelvis, and extended upward, parallel to the normal ureter and inside of it. It was full of foul pus and was cut close behind the bladder, while after removal of a section of it the upper end was brought out of the upper angle of the incision (extraperitoneal) and fixed to the skin. Later the left kidney was removed and the patient finally recovered. The author finds that unilateral duplication of a ureter is a fairly common anomaly, while an abnormal opening of the lower end (as in the present case) is rarer and of greater surgical interest. The abnormalities are all referable to the very complicated shifting which occurs when the Wolffian duct and the developing ureter cease to enter the allantois by a common opening. Such a case as the one recorded, with the lower opening of the ureter in the prostatic urethra, give no symptoms unless infected. Infection of a badly drained ureter quickly involves the kidney, and hence the local signs and symptoms all point to an involvement of this organ. Summarized histories are given of several similar cases. The condition is one the possibility of which should always be considered by the surgeon when he is confronted with a case of atypical urinary suppuration.

New York Medical Journal, September 21, 1907.

Advantages and Limitations of the X-ray in the Treatment of Surgical Tuberculosis.—H. K. Pancoast contributes a lengthy article on this subject. He declares that while there is no proof that the *x*-ray has any direct effect upon the *Bacilli tuberculosis,* there is abundant evidence of the value of the ray in modifying and treating tuberculous lesions. The local tissue modifications as observed in lupus cases under ray treatment are described in full. The term "cure" as applied to these cases has an elastic significance. Some cases are cured spontaneously. Judicious application of radiotherapy to tuberculosis or any other disease calls for the observance of certain cardinal principles enumerated as follows: (1) A reaction of the tissues of the body to the *x*-ray is manifest in those tissues only in which the rays are absorbed. By the use of the proper tube, together with correct manipulation of the apparatus, the degree of penetration of the greater number of the rays generated may be determined and controlled to a great extent. (2) The first effect of radiation upon normal tissues is stimulation, followed by irritation, inflammation, and finally by cellular destruction. (3) The applications should be so administered as to secure that reaction which is necessary or most efficient in bringing about the desired results in the treatment of any disease. (4) In normal tissues the destructive effect is first manifest in those cells which are most highly specialized, as the epithelium of the glands and hair follicles of the skin, and the spermatogenic cells of the testicle. (5) In diseased structures it is first manifest, usually, in those cells which are distinctly pathological and of a lower vitality than the normal tissue cells. In treating certain lesions, such as those of tuberculosis, more than one reaction is often desirable. Superficially, we may go so far as to produce an inflammatory reaction in the healthy structures, but in the case of the deep lesions we must usually stop at stimulation. The exposures required for these reactions should, when possible, be destructive to diseased cells of lowered vitality. The author then passes in review the various surgical conditions in which radiotherapy has been tried and gives a fair estimate of its possibilities in the various clinical conditions. He believes that we must now recognize it as a rational and efficient means of treating many local lesions. With the possible exception of lupus, however, it is but an adjunct to other forms of treatment.

Nephroptosis.—J. Ullman gives a general description of this condition, quoting statistics as to its frequency, and discussing its various modes of production. Some cases give no symptoms. Those presenting symptoms fall into two main groups, the genitourinary and the gastrointestinal. The various symptoms of these two main classes of cases are given. Ullman gives the following rule for palpating for a movable kidney: Place the patient in a reclining position with the chest slightly elevated and the thigh drawn well upon the body. Place the left hand on the loins, while with the right hand you feel the kidney, the patient breathing deeply. Sometimes a change of posture, such as from right to left recumbency or a knee-chest position, and returning to the orignal posture, will assist in finding a nephroptosis. Certain tumors must always be thought of in palpating. There are hydrops of the gall-bladder, the "corset" liver, so-called, carcinoma of the liver or stomach, hydatid of the liver, visceral lymphosarcoma, malignant growth of the kidney itself, ovarian cysts, omental tumors, appendicitis, wandering spleen or liver, fecal impaction, and intussusception. Apart from those cases in which the kidney has become fixed in a faulty

position, a proper corset or belt will relieve the symptoms. Directions for diet are given for those cases attended with special debility. If there has been much emaciation or if the nervous symptoms are especially prominent, the patient should be given plenty of rest at the outset before more active measures are instituted. The paper closes with a lengthy bibliography.

Juvenile Paresis.—One case is reported by M. J. Karpas, whose patient was a young woman of twenty-three years of age, who probably had inherited specific disease. Her first symptoms of mental alienation began at seventeen. She first came under the author's observation in 1905. A full description of her physical and mental condition at that time is given. She remained in confinement until her death, some twenty months later. In referring to the clinical manifestations of paresis in juveniles the author notes certain atypical signs as of frequent occurrence. Thus optic atrophy is quite common. Paralytic attacks may occur and accompany the disease process and may ever be the initial symptoms. Convulsions naturally appear in the later stages of the disease. The mental picture is one of progressive dementia. Delusions may be present at the outset. Ideas of grandeur are rare, delusions of persecution are possible. Hallucinations are infrequent, depressed states are uncommon, while hypochondriasis is rare. Remissions are unusual and the course is slowly and progressively worse. The final stage is reached in about four years. Commenting on the rarity of this malady in juveniles, Karpas states that in 1902 there were but 80 juvenile paretics reported in literature.

Journal of the American Medical Association, September 28, 1907.

Hemoptysis Due to Tuberculosis.—J. M. Anders says we are apt to ascribe any early pulmonary bleeding in consumptives to congestion of the bronchial mucosa, but it is probable that minute areas of necrosis already exist when these bleedings occur. That a high grade of congestion, however, is a factor is shown by the influence of physical strain, and the heart's condition must be also considered. Patients with chronic valvulitis undoubtedly have more frequent hemorrhages. Hemorrhages from eroded vessels and miliary aneurysms are the more frequent causes of fatal results, and less frequent occurrence of pulmonary hemorrhage in advanced cases of consumption is ascribable to endarteritis, causing gradual thickening and greater resistance of the vessel walls. Undoubtedly there is in many cases an existing hemorrhagic tendency and hereditary taint is often obvious. Aggravation of the cough and muscular exertion are frequent exciting causes. Anders points out that the frequency of the symptom is very marked. His own experience does not show greater frequency in females than in males, and he says that sexual differences are not as great in this regard as has been claimed. Season has a decided influence, as shown by his table. More cases occur in the spring and summer months than in the winter. The attack does not seem to have any marked effect in reducing temperature in the majority of cases, and sometimes there may be a notable rise, due to exacerbations of tuberculous inflammation from the setting free of toxins, etc. The majority of bleedings occur after secondary infection with the streptococcus. Prophylactic measures are unduly neglected. The importance of rest and of avoidance of stimulants is hardly duly appreciated. A residence away from the seacoast and a cold dry aseptic air are beneficial, as pointed out by Curtin. Among drugs, he relies mainly on opium, discontinuing it if abundant moist bubbling râles are heard over the uninvolved portion of the lung—a rare event, except in case of rupture of a miliary aneurysm. In case there should be a ruptured aneurysm, with profuse hemorrhage and danger of inundation of the uninvolved lung, cough should be encouraged rather than suppressed, and opium is contraindicated.

Systemic Blastomycosis and Coccidioidal Granuloma.—L. Hektoen gives a summarized account of the published cases and comments on their special features. It would appear that the respiratory tract was the point of entrance of the infection in many cases, and this is a suggestion of its air-borne nature. The presence of blastomycosis in the sputum in some cases also suggests a possibility of contagion in this way. The pathological lesions and the organisms are described in detail. The latter are placed in the genus *Oidium* by Ricketts. The "protozoic skin disease" of Wernicke and the coccidioidal granuloma of Ophüls are also considered and abstracts of the reported cases are given, and their characteristic features described. The organisms of both blastomycosis and this disease are evidently closely related and the disorders resemble each other in many respects clinically and anatomically, but there are certain constant and distinctive peculiarities in each: 1. The nodular lesions of coccidioidal granuloma bear a closer resemblance to the typical, specific tubercle than the nodules of blastomycosis. 2. In coccidioidal granuloma there is marked tendency to involvement of the lymph nodes, in blastomycosis slight. There is also a difference in the organisms; in blastomycosis they multiply by budding, in the other disease by endogenous sporulation. Neither forms mycelium in the animal body.

Boston's Campaign for Clean Milk.—J. O. Jordan gives a history of the campaign inaugurated by the Boston Board of Health in 1904. The initiatory step was the adoption of a standard limiting the number of bacteria in milk to 500,000 per cubic centimeter and prohibiting the sale of milk having a temperature above 50° F. The bacteriological examination also permits the detection of milk from diseased animals and following up of the infection to the dairies themselves. The contracting firms have cooperated with the Board of Health to a considerable extent by inspection of dairies, distribution of circulars of information to producers, and even by the establishment of private laboratories. The Massachusetts State Board of Health also exercises supervision over the dairies and cooperates with the local board. The result has been a great improvement in the milk supply of the city. A possible outcome of the agitation of the milk question is the centralizing of the milk supply in cities in the hands of large concerns and the present tendency is toward such a result. The education of the public as to the necessity of clean milk is, however, the matter of the greatest importance of the present time.

The Milk Supply of Washington, D. C.—G. L. Magruder gives an account of the measures taken to secure a proper milk supply in the city of Washington during the past year. The prevalence of typhoid fever had called attention to the milk supply, and an investigation by the Bureau of Public Health at the instance of the District Commissioners had revealed a deplorable state of affairs, ten per cent. of the cases of fever being directly traceable to milk infection. In September, 1906, Dr. Magruder had a conference with the Secretary of Agriculture, whose interest was aroused and an inspection of dairy farms was instituted as had been recommended by a committee of the medical society of the District as far back as 1894. Remarkable conditions were found to exist. The water supply of sixty dairy farms, taken without selection, was found unsafe in as much as twenty-five per cent.; forty-five per cent. showed the presence of the colon bacillus. The investigations have been followed up by both the Department of Agriculture and Public Health Bureau, and the result has been the organization of the District Milk Commission under the chairmanship of ex-Surgeon-General Sternberg of the army, and including in its members a number of the scientific officials of the Health Bureau and the Agricultural Department.

The Early Diagnosis of Tubal Pregnancy.—P. A. Harris says twenty-nine out of every thirty cases of ectopic pregnancy present symptoms warranting a presumptive diagnosis of the condition before it becomes alarming. He found, however, from a study of 130 cases that while ninety per cent. of the patients consulted physicians before the tragic stage was reached only about twenty per cent. of the physicians arrived at a correct presumptive diagnosis, and many of the patients were wrongly advised of threatened abortion or were subjected to curetting for metrorrhagia, the cause of which was not suspected. The general answer he has given when asked how to diagnose ectopic pregnancy is as follows: "When any woman after puberty and before the menopause, who has menstruated regularly and painlessly, goes 4, 5, 6, 8, 10, 15, or 18 days over the time at which menstruation is due, sees blood in the vagina differing in quality, color, quantity, or continuance from her usual menstrual flow, and has pains, generally severe, on one side of the pelvis or the other, or possibly in the hypogastric region, ectopic gestation may be presumed." The blood of the ectopic pregnancy hemorrhages has a peculiar slippery feel, and the pains also differ markedly from those of ordinary dysmenorrhea. The pulse and temperature, except in cases of excessive bleeding, are not likely to be affected in the non-tragic stage. The tragic stage is ushered in by severer pains, pallor, weak and rapid pulse, lowered temperature, fainting, generally vomiting and restlessness, and sometimes a lethargic condition from which the patient can be roused. The findings of the physical

examination and the differential diagnosis from abortion, salpingitis, polypus, uterine cancer, ovarian cyst with twisted pedicle, and intrauterine pregnancy with metrorrhagia are detailed and six case histories are given. In his concluding remarks, Harris insists on the importance of thorough and accurate history taking in these cases, especially as to the character of earlier menstruations for a number of months preceding the symptoms. As soon as diagnosis is made, operation is indicated. In dealing with women in the non-tragic stage, the advice to them should be governed by the consideration that from one-half to two-thirds of all cases of ectopic gestation, uninfluenced by operation, eventuate in death, but that with prompt and proper operation ninety-nine per cent. of the patients ought to recover.

The Syncytium.—Laura H. Branson says the syncytial tissue is of fetal origin; it is in direct line from the ectoderm or trophoblast. The chorionic villi or parts of them, together with their epithelial covering, may circulate normally in the blood and lymphatic circulation of their host during pregnancy. The epithelial covering has the power to proliferate during the entire life cycle of the syncytium and Langhans' cells. The syncytium has a physiological function, but failing in this, its pathology may be detrimental to both fetus and host. It is the prime factor in the production of a peculiar neoplasm whose histology places it in a class by itself, viz., syncytioma malignum. Recent investigations also support the view that the syncytium is the prime cause of eclampsia; it is the one cause that can meet all claims made by recent investigations and theories. Hepatic changes are the rule, not the exception, in eclampsia. Malignant neoplasms of pregnancy have an eroding action on the uterine structures; this is the nature of the chorionic epithelium covering the villi normally. Chorionic epithelium is one of the pathological constituents of these neoplasms, and it is reasonable, therefore, to conclude that their origin is the same and that this activity continues in force in the neoplasms.

The Lancet, September 14, 1907.

The Polymastia of the Japanese.—A statistical study of this subject is made by T. Iwai, whose conclusions are as follows: (1) Among the Japanese, unlike the Western people, polymastia is generally found above the normal breasts, and most commonly on the anterior wall of the axilla, or above and external to the normal breasts along the front edge of the axilla. (2) It is likely that in many cases of polymastia the areolæ of those under the normal breasts are pigmented, and that in males they are more likely to be pigmented than they are in females. (3) According to the result of investigations made by the author and others up to the present time, the rate of polymastia is 1.68 per cent. among males and 5.19 per cent. among females. The fact that they find it more frequently in females than in males, and on the left side than on the right, exactly coincides with the results obtained in the West. (4) Six is the largest number of glands yet found on one person. (5) It is certain that polymastia is inherited and in most cases is transmitted from mothers. (6) In the perfect supernumerary mammary glands the secretory process begins at the time of parturition and sometimes it continues for over six months. The paper closes with an elaborate bibliography on the general subject of polymastia.

Spontaneous Aneurysm of the Popliteal Artery Treated by Extirpation.—The patient of H. A. Lediard was a man of fifty-four years, laborer, who three months previous to coming under observation had strained his right knee and had had, subsequently, pain in the knee and calf while at work. Two weeks before admission to hospital a swelling came on the popliteal region and grew rapidly. When seen it was pulsating, fusiform, and expansile, while both thrill and murmur were present. Incision was made six inches long over the popliteal space, the artery dissected out, ligated above and below, and the segment exsected. Some difficulty arose in separating the popliteal vein from the aneurysmal sac. The patient made a good recovery and left the hospital in about three months, able to kneel slowly without pain and to walk with only a slight limp. Three months later he was able to walk several miles without a cane and to do light work, as gardener, etc. The author refers to recent literature on the subject of aneurysms.

Actinomycosis of the Appendix.—Notes of five cases (three of them personal) are given by A. R. Short, who finds about 150 cases on record and believes that many cases have been recognized, but not published. Foreign bodies carrying the infection have been found in five instances. An analysis of 80 cases shows the disease most common between twenty and thirty years. The sex proportion is about five male to two female. Three types are described: (1) The mucous membrane may be very extensively ulcerated, forming the principal if not sole localization of the disease. (2) The wall of the appendix and cecum may be greatly thickened without perforation or extension. (3) Perforation is the usual sequence. Acute general peritonitis does not result, but abscesses form and track freely in all directions, enclosed by adhesions of very extraordinary density, more so that in any other abdominal condition. In one of the author's cases the peritoneum was half an inch thick. The author presents the grouping of symptoms arranged originally by Hinglais, viz.: (1) Initial period of visceral manifestations, vague pains in the right iliac fossa, sometimes associated with intractable diarrhea, which may be mucomembranous in type. Pain may be severe and a diagnosis of relapsing appendicitis is likely. There are no local signs. (2) Stage of fever formation. (3) Fistula formation. Abscesses burst or are opened in the neighborhood of the original site and dark fetid pus discharges. In this the granules may be found, but they are very often absent, especially if the discharge is fecal. The best time to look for them is when a new abscess is opened. This stage usually lasts for months, subphrenic or pulmonary abscesses form, and the patient dies from hectic fever and exhaustion. In some cases, however, there is— (4) A stage of cicatrization. The fistulæ close and cure results. Unhappily this is often only temporary. Diagnosis is assured only by finding the actinomyces in the stools. Prognosis is uncertain. Of a series of 71 cases, 22 were cured, 10 relieved, and 45 died. Treatment calls for the removal of all foci of infection. The cecum and neighboring bowel must be sacrificed if necessary. Mere opening of abscesses is not sufficient.

Irregularity of the Pulse in Diphtheria.—O. H. Peters claims that irregularity of the pulse in diphtheria in children is really of little special significance, being due to the great incidence of the disease in the early years of life, especially the fourth and fifth years. Children at this age, he says, commonly exhibit this symptom in any febrile disturbances and often in apparent health. The irregularity is very common indeed, it being found in over eighty per cent. of the author's cases. Comparisons of similar numbers of diphtheria and scarlet fever cases showed about the same percentage of cardiac irregularity. The irregularity is referred by various authorities to a nervous origin rather than a cardiac. There seems to be an excessive susceptibility in the inhibitory action of the vagus, and it is believed that the rhythmical stimulation of the respiratory center has a rhythmical effect on the vagus center. Peters refers to Barr's explanation *vs.* the mechanical effect of the respiratory act on the circulation. The fall in blood pressure in disease is undoubtedly the primal cause setting up the irregularity. If actual myocarditis is present an irregular pulse is of course of the gravest significance. In most diphtheria cases with irregularity the latter continues during hospital stay and the children are kept in bed week after week when they would do better if in the open air, which would certainly improve their anemia. We must first carefully assure ourselves that the irregularity is more than respiratory. The presence or absence of cardiac signs will help decide this point.

British Medical Journal, September 14, 1907.

The Treatment of Sleeping Sickness and Other Trypanosomiases by the Arsenic and Mercury Methods.—Sir R. Boyce reviews the history of clinical results with arsenic-acid anilid and declares that all authorities now unite in giving it the first rank as a trypanocide. Quite recently it has been demonstrated that even better and more lasting results than those obtained by atoxyl alone are obtained by treating injected animals from which the trypanosomes have primarily been driven out by atoxyl, by a second drug which will prevent the recurrences which so often follow the atoxyl treatment alone. The salts of the heavy metals were proven to have no marked results in this direction until the mercuric bichloride was used, whereupon a distinct benefit was immediately noted. Boyce believes that the application of a biochemical principle may prove to be of wide range in the therapeutics. Various protozoa have distinct phases in their life history and the drug which proves efficacious in the first phase or stage may prove powerless in the second, or *vice versa*. Such a sequence of remedies may not be arsenic-mercury, but this especial experience is a brilliant illustration of the principle. The mercuric salt alone has not the slightest effect upon the ordinary phase

of the trypanosome, as seen on the peripheral circulation and upon which the atoxyl has such a prompt and decided effect. This would appear to clearly demonstrate that the two drugs act upon two quite distinct phases of the life of the trypanosome.

Myelopathic Albumosuria.—One case is reported by A. L. Brown—that of a Jewish man of fifty years, complaining for about a year with pains in the hands and legs. Later all over the body. Examination showed anemia, tenderness of the ribs on percussion, intense pain on being moved, some bronchitis, and an albuminous body in the urine. This latter body was determined to be the albumose described by Bence Jones. Hard nodules soon appeared on the ribs over the previous painful areas, hard movable glands in the right axilla, diarrhea set in, the urine became scanty, and the patient died in about a month. No autopsy was permitted. The author describes the tests leading to the detection of the albumose and believes the case to have been one of myelopathic albumosuria, or Kahler's disease. This form is always associated, the author believes, with diseases of the bone marrow. He denies that albumose is alimentary in origin because (1) proteolysis normally proceeds beyond this stage, the terminal products being hexone bases and amino acids; (2) the B.-J. albumose reactions are not identical with the digestive albumoses; (3) a considerable alteration of diet has no effect on the amount of proteid excreted (confirmed in the author's case); and (4) the alimentary view does not explain why marked and persistent albumosuria should appear in this particular variety of malignant disease. In this particular case the diagnosis was for a time obscured by the fact that there coexisted a true albuminuria with hyaline and granular casts. Death apparently resulted from a terminal pneumococcic infection.

The Eyesight of the Poorer City Children.—The paper of H. W. Thompson is the result of inquiries made concerning the school children in Glasgow. The initial test was made by the teacher, who reported 35 per cent. of the pupils with defective vision in one or both eyes. It was found that children in schools nearer the open country could see better than those in the heart of the city, and presumably poorer. This defect of sight is not due to any physical abnormality of the eyes, but seems to be due partly to want of training and partly to malnutrition. The effect of the want of training might be, to some extent at least, neutralized by certain modifications of the infant department curriculum at school, notably by abolishing sewing and all forms of work which require close poring over, and by instituting suitable visual exercise games. The effect of malnutrition might be combated by proper feeding during school life, as the author has found it to be in the industrial schools which he investigated.

Berliner klinische Wochenschrift, September 9, 1907.

Mongolian Pigmentation in Two Berlin Infants.—Tugendreich explains that whereas as long as it was supposed that the peculiar pigmented spots occurring a little above the anus in Japanese infants were a racial characteristic the Japanese were proud of the mark and regarded it as an evidence of especial distinction. Further investigations have shown, however, that the accumulations of pigment cells forming the spots are also found in the other Mongolian races and to some extent in nearly all monkeys. The spots therefore are considered as being connected with the evolution of the human being, and it has been suggested that the races exhibiting them to the most marked degree are nearest to the lower forms. Accordingly the Japanese have been anxious to demonstrate the presence of similar marks in members of other races and have succeeded in doing so in many instances. Adachi found the pigment cells ten times in examining the bodies of twenty-four infants in Strassburg. Epstein estimates that the pigmentation may be seen in one out of about 600 white infants. Tugendreich has seen it twice out of 1,200 cases and says that even although a certain racial characteristic may sometimes occur in other nationalities it does not therefore lose its value as a distinctive mark, for even the relative frequency with which it occurs may be looked upon as a typical sign. It is interesting that the spots have been quite often found among Hungarian children and the relationship between the Magyars and Mongols is pointed out in this connection. Apparently in the instances that have been reported of pigment spots in white infants the individuals have all been of the dark type, with brown skin and brown iris.

Münchener medizinische Wochenschrift, September 10, 1907.

The Pathogenesis of Hirschsprung's Disease.—Neter says that in spite of the numerous modifications which the conception of this affection has undergone in the last few years, it may be defined as being a type of constipation appearing in earliest infancy, often during the first days of life, that is extremely obstinate and is not rarely fatal. Anatomically there is always found a marked dilatation of the lower portion of the colon, particularly of the sigmoid flexure, and usually also an abnormal dilatation of this portion of the intestine. Hirschsprung assumed that the dilatation and hypertrophy of the sigmoid were congenital, but some observers had advocated the view that there is a congenital dilatation of the lower portion of the colon with aplasia of the musculature. Others have believed in an idiopathic dilatation of the colon or in deficient tonus of a normal muscular wall in consequence of inadequate innervation. The author is of the opinion that the fundamental condition leading to the development of Hirschsprung's disease consists in an abnormal length of the sigmoid and that the dilatation and hypertrophy are secondary and not congenital changes. A case in point is reported which the author regards as affording evidence in favor of his theory.

The So-called Acquired Lymphangiomas of the Neck.—Dencks states that cavernous lymphangiomas of the neck are rather rare as a congenital condition, and are much more so as neoplasms appearing later in life. He has been able to find only six instances of the latter sort, and numerous authors, as a matter of fact, do divide the congenital and acquired lymphangiomas of the neck into two distinct classes. The author describes two cases of cystic lymphangioma first appearing during adult age, and as the result of the analysis of these, as well as of the other cases reported, he reaches the conclusion that the distinction between the congenital and so-called acquired growths is not tenable and that both genetically and morphologically the neoplasm is the same in each case. The germ of the new growth must be assumed as existing congenitally and the difference consists only in the time at which the growth becomes independent. While in most of the cervical lymphangiomas development occurs during intrauterine life, so that a tumor is already present at the birth of the fetus, in some instances the latent germ develops into a tumor only later in life. Why this peculiar course is sometimes observed cannot be explained, but it appears that the period of puberty has something to do with the development of the lymphangiomas, as is the case in the branchiogenetic cysts.

French and Italian Journals.

Palliative Treatment of Cancer of the Cervix Uteri.—F. Jayle says that in many cases of advanced and inoperable cervical cancer the only palliative treatment that is justifiable is the curetting of the fungosities and cauterization of them with a hot iron. In women who are still menstruating the progress of cancer is more rapid than in those who have passed the menopause. Therefore it is of advantage to the patient that the uterine circulation should be modified. It has been advised for this purpose to ligate the uteroovarian arteries, but this is very difficult on account of the extensive lesions. The best procedure is laparotomy, with removal of the ovaries to stop the internal secretion which prevents atrophy, and combined with it the ligation of the hypogastric arteries. Curettage and cauterization of the fungosities may be done at the same time.—*La Presse Médicale*, May 25, 1907.

Delivery by Bossi's Dilator in Eclampsia.—R. Schockaert believes that rapid delivery is the only rational means of treatment of puerperal eclampsia. In primiparæ with closed cervix and labor not yet begun it is necessary to dilate in some way. The author believes that the best method is by means of Bossi's dilator, used carefully, and slowly, with frequent digital examination to ascertain the progress of dilatation. The advantages of this instrument are ease of manipulation, lightness, ease of disinfection, ability to dilate slowly and to ascertain progress by reading off the scale on the instrument, and cheapness.—*Bulletin de la Société Belge de Gynécologie et d'Obstétrique*, Vol. XVIII., No. 1, 1907.

Elimination of Sulphur from the Urine of Sulphur Miners.—Francesco de Grazia has examined the urine of young and healthy sulphur miners who are in a constant sulphur dust and may be supposed to absorb the chemical if such absorption is possible. He estimated the total sulphur, acid sulphur, and neutral sulphur. He found that there were two modifications in the elimination of sulphur in these men: increase of total sulphur, with predominance of acid sulphur, as in normal conditions; and more rarely increase of neutral sulphur with increase of total sulphur elimination. These workers live very sparingly and the increase of sulphur elimination could not result from increased ingestion of proteids on account of the poverty of the workers.—*La Riforma Medica*, June 22, 1907.

Book Reviews.

Précis de Pathologie Interne. Par MM. Balthazard, Cestan, H. Claude, Macaigne, Nicolas, et Verger, Agrégés des Facultés de Médecine. Préface de M. le Professeur Bouchard. Four Vols. Paris: Steinheil, 1907.

Six of the younger teachers, agrégés at the various medical schools of France have united in producing this work, a textbook of internal medicine in four volumes. The names of the authors are well known to those who have followed the current literature of recent years, especially those of Balthazard, Claude, and Macaigne. The book is an exposition in concise yet quite sufficiently full form of the internal diseases from the viewpoint of modern clinical and experimental research. The first volume deals with infectious diseases (Nicolas) and the intoxications (Balthazard); the second is devoted to diseases of nutrition, blood (Balthazard), heart, lungs (Macaigne); the third to maladies of the digestive (Balthazard) and urinary organs (Claude); the fourth entirely to nervous diseases (Cestan and Verger). A feature of the book is that the several authors having studied and worked together and having been nominated agrégés at the same competition are quite in accord with one another in their views, and that consequently there is more uniformity in the various portions of the work than is usually obtainable in a book composed by a number of men. While much might be said in praise of the various portions of the work, we shall have space enough here only to call attention to the new plan of classification adopted in the volume on nervous diseases. Instead of studying these diseases according to the old anatomo-physiological scheme, an attempt is made to classify them according to modern pathological and etiological data. Thus acute inflammations are grouped together, meningitis, encephalitis, myelitis, poliomyelitis, etc. Then the chronic inflammations, the scleroses, including tabes, etc. This method of study is new in neurology, although it obtains in all other branches of medicine. The style of the book is very clear and easily grasped, and we would recommend its reading as a means of gaining a very good knowledge of medical French, as well as a source of enlightenment upon many of the puzzling themes of medicine in which modern research is gradually making its way.

The Röntgen Rays in Medical Work. By David Walsh, M.D. Ed., Senior Physician, Western Skin Hospital, London, W.; Hon. Physician and Senior Physician to the Skin Department, Kensington General Hospital; Late Hon. Secretary Röntgen Society, London. Part I. The Electrical Apparatus. By H. Lewis Jones, M.D. Cantab., F.R.C.P. Lond. Medical Officer in Charge of the Electrical Department, St. Bartholomew's Hospital. Part II. Medical and Surgical. By the Author. Fourth Edition. New York: William Wood & Company, 1907.

In part I is given a description of the electrical apparatus, such as the *x*-ray tube, the static machines, induction coils, secondary battery or accumulator, direct application of the mains, accessory apparatus, practical working of the *x*-ray apparatus, localization, and stereoscopic radiography, all of which is illustrated by sixty-two pictures. Part II deals with the medical and surgical applications. The systematic manner in which the author deals with this subject is shown by the following classification, which covers most of the ground broken by this modern means of accurate investigation: A. Surgery. I. Foreign Bodies. II. Bones. III. Mapping of Skin Surfaces. B. Dental Surgery. C. Nasal and Throat Surgery. D. Medicine. IV. Regional. V. Other Medical Points. VI. Action on Skin and Deeper Structures. VII. Therapeutics. E. Obstetrics and Gynecology. F. Legal Medicine. G. Anatomy. H. Physiology. I. Veterinary Uses. One hundred and ten pictures illustrate this part of the work. This book should be in the hands of all who are doing *x*-ray practice.

Ueber die Psychologie der Dementia Præcox. Ein Versuch. Von C. G. Jung, Privatdozenten der Psychiatrie in Zurich. Halle a. S.: Carl Marhold, 1907.

We recommend this suggestive little book to all students of psychiatry. It is in line with the author's studies on association and will be of especial interest to those who have followed his work and the work of Freud and Bleuler in psychogenic disorders. It is based on three years' clinical and experimental observations and comprises chiefly an attempt at a psychological analysis of dementia præcox by tracing all symptoms to their genesis. The mentality in dream states and hysteria is also analyzed and compared with the mechanism of the psychological disorder in dementia præcox. The book is instructive and shows considerable originality.

The Integrative Action of the Nervous System. By Charles S. Sherrington, D.Sc., M.D., Hon. LL.D. (Jor.), F.R.S., Holt Professor of Physiology in the University of Liverpool, etc. With Illustrations. New York: Charles Scribner's Sons, 1906.

The substance of this book was contained in the Silliman lectures delivered by the author at Yale in 1904. The subject constitutes a most important phase of neuro-physiology, and is best defined in the author's own words: "In the multicellular animal, especially for those higher reactions which constitute its behavior as a social unit in the natural economy, it is nervous reaction which par excellence integrates it, welds it together, from its components, and constitutes it from a mere collection of organs an animal individual. This integrative action, in virtue of which the nervous system unifies from separate organs an animal possessing solidarity, an individual, is the problem before us in these lectures." The lectures consider in turn the coordination of simple reflexes, the interaction between reflexes, the combination of reflexes, simultaneous and successive; reflexes as adapted reactions, the reactions of the motor cortex, the physiological position of the brain in the integration of the nervous system, and sensual fusion, *i.e.* integration in relation to sensation, as exemplified in the simple phenomenon of binocular vision. A very full bibliography is appended. The book will appeal to the special student of physiology and to the neurologist who likes to know the scientific basis of nerve phenomena. The lectures are written in a fascinating manner, without dryness, and are well illustrated with charts, etc.

The Miracle Worker. By Gerald Maxwell. Boston: John W. Luce & Company, 1907.

Whatever may be the reader's opinion of the singular method chosen by Dr. Ahmed for restoring the comeliness of the beautiful Countess Lichtenthal after a frightful burn had disfigured her charming features, we are sure that he will follow with the greatest interest the complicated steps by means of which this gratifying result was finally attained. A new anesthetic, the power of suggestion, experimental physiology, and transcendental cerebral surgery are among the ingredients of which this ingenious tale is compounded, and the author's acquaintance with medical and surgical matters is so intimate as to make it seem more than probable that he is the possessor of a degree which does not appear on the title page. The atmosphere of the German University City and of court life in a minor principality is cleverly reproduced, but we must protest that it is impossible to believe that any well-educated young German woman should be, like the heroine, ignorant of the authorship of the classical "Maria Stuart." That is a slip we feel no Teuton will readily forgive.

A Manual of Surgery for Students and Physicians. By Francis T. Stewart, M.D., Professor of Surgery, Philadelphia Polyclinic; Associate in Surgery, Jefferson Medical College; Surgeon to the Germantown Hospital; Out-patient Surgeon to the Pennsylvania Hospital. With 504 illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

In this volume will be found a concise and fairly complete statement of all the surgical facts and details required by the physician and undergraduate. Though small, the book contains a large amount of information, the whole of which has been well selected, well arranged, and amply illustrated. Due emphasis is laid on matters of clinical importance; the fundamental principles of general surgery are clearly dealt with, and the teaching represents the generally accepted methods of modern surgery. No space has been taken up by historical or bibliographical details. For a long time there has been a demand for a manual of this sort, as the previous successful attempts along this line (one or two in number) have outgrown the position for which they were originally designed; and the majority of the compends on surgery are too meager and incomplete to be of any real value. The main use of the present volume will be as an aid to the student in following lectures, or in preparing for recitations; also in preparation for the State board or other examinations.

La Cure de Déchloruration dans le Mal de Bright et dans quelques maladies hydropigènes. Par le Dr. Fernand Widal, Professor Agrégé à la Faculté de Médecine de Paris, Médecin de l'Hôpital Cochin et le Dr. Adolphe Javal, lauréat l'Académie de Médecine. Paris: J. B. Baillière et Fils, 1906.

In this pamphlet will be found an account of the dechloridation treatment or salt free diet in nephritis, and also in some other conditions, chiefly of cardiac origin. Whether or no the chlorides should be withheld from the diet of nephritics is a question that is still under discussion, and the authors of this monograph present their side of the subject with much ability.

Society Reports.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS.

Held at the Academy of Medicine, New York City, September 9 to 14, 1907.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 543.*)

Gangræna Cutis Hysterica.—By Dr. H. P. TOWLE of Boston. This paper dealt only with those cases of gangrene of the skin which were either of artificial or of so-called spontaneous origin. It did not consider the cases of gangrene which occurred in childhood or which were due to such causes as bacteria, organic diseases of the nervous system, or to obliterative diseases of the vessels. The paper gave the clinical histories of four cases of multiple gangrene of the skin, three in women and one in a man. While the cases varied somewhat from each other in minor details, they were alike in their essential features. They occurred in patients who were more or less markedly hysterical. Each case had suffered some sort of trauma before the appearance of the first gangrenous lesion. The first manifestation was in the immediate neighborhood of the preceding injury. After varying intervals of freedom, new lesions appeared farther and farther away from the starting point, as time went on. The affection had existed for months, and in one case for years. The changes in the skin from the time of the first appearance of the lesions until they became gangrenous were very rapid, while, on the other hand, healing was very slow. Recurrences never occurred when the patient was under control, and the affection never involved the parts which were not readily accessible. The physical examination showed nothing which would account for the changes in the skin. It was believed the eruptions were all feigned, but the evidence remained purely circumstantial, as none of the patients would confess and nothing was ever discovered with which the lesions could have been produced.

Prof. E. GAUCHER of Paris, France, said that not long ago he was the only one, with Prof. Raymond, to defend the existence of gangræna hysterica. This condition, he thought, should not be stricken from our nosology. Of course, the gangrene was a secondary phenomenon, caused by infection of a slight abrasion of the cuticle, but hysteria prepared the ground on which the gangrene developed. Despite the necessity of an initial lesion, hysteria was absolutely an essential factor. This was enough to justify the maintenance of gangræna hysterica as a separate morbid entity.

The discussion was continued by Dr. H. Radcliffe-Crocker of London and was then closed by Dr. Towle.

Afternoon Session.

DR. F. J. SHEPHERD OF MONTREAL, VICE-PRESIDENT, IN THE CHAIR.

The Etiological Relationship of Organisms Found in the Skin in Smallpox.—Prof. W. T. COUNCILMAN of Boston, in discussing this subject, said the cause of smallpox was believed to be a parasitic organism having its habitat in the epithelial cells of the specific lesions of the skin. It was first recognized by Guarnieri and named by him *Cytoryctes variolæ*. It was described in more detail by Councilman and his coworkers in 1904, and a probable life cycle was established by Calkins. The organism underwent a definite development within the skin, certain forms corresponding with the period of eruption. The same organism up to a certain period of development was found in vaccina. Certain stages of development were peculiar to smallpox and found only in the lesions of that disease. It was believed that there were probably two cycles of development: (1) An imperfect cycle, probably analogous to the asexual cycle of the coccidia, which was common to both vaccina and smallpox; (2) a complete cycle, representing a further development of the vaccine cycle, which was only found in smallpox. The virus of smallpox differed from that of vaccina in its capacity of transmission without contact. The monkey was susceptible to the smallpox virus, and inoculation with smallpox material (contents of pustules) produced a disease with the specific lesions of smallpox and with a complete cycle of the parasite. Inoculation of the rabbit or calf with smallpox material produced a disease comparable to vaccina, and with the incomplete or vaccine cycle of the organism. The inoculation smallpox of the monkey could be transmitted from animal to animal. The vaccina produced in the calf or the rabbit by inoculation of smallpox material was transmitted as vaccina from animal to animal. Monkeys had been shown to be susceptible to smallpox only by artificial inoculation. It was not possible to infect them by means of exposure. The inoculated disease produced in monkeys had the same period of incubation as variola inoculata in man. In addition to the skin lesions, lesions specific to the disease were also found in the bone marrow and in the testicle. All other lesions of the disease were not specific, and were to be attributed either to the action of toxins or to the action of infectious bacteria, chiefly streptococci. Both vaccina and smallpox led to active hyperplasia of the lymphoid tissues, with the production of large mononuclear lymphoid cells which passed from the lymph nodes into the blood.

Prof. GARY N. CALKINS of New York City said he would interpret the organism of smallpox as a rhizopod in which only one phase of the life history was known, namely, the asexual or vegetative phase. This was characterized by development of the chromidium and formation of small reproductive spores ("gemmules"), which repeated the cytoplasmic cycle. The intranuclear forms possibly belonged to the sexual cycle, and it was not improbable, as Councilman had early suggested, that the intranuclear forms might be a different cycle of the organism occurring in variola and not in vaccina. He would interpret the vesicular forms as either poorly fixed organisms, or as degenerated forms of the organism, the degeneration being produced by the accumulation of toxins found in the breaking-down vesicle. In any event, the intranuclear forms of the organism presented a different history from that of the cytoplasmic forms, and this history remained for some one to work out on well-fixed tissue, or, better still, on the living organism.

Dr. WALTER R. BRINCKERHOFF of Honolulu said that unfortunately the only animals available for experiments upon the modes of the transmission of smallpox were the monkeys, and in them we could produce only one form of the disease. To do more effective work in the study of the transmission of the disease from man to man, it would be necessary to produce true variola, and for that purpose it would be necessary to have monkeys that were nearer to man than the species previously experimented on. If we could produce variola vera in one of the lower animals, we would be able to undertake definite work bearing upon the therapy of the disease. That form of the disease which could now be produced in the monkey was never fatal.

Dr. THOMAS C. GILCHRIST of Baltimore referred to the similarity this organism bore to certain cell degenerations, which he had found particularly well demonstrated in benign growths of the skin.

Prof. COUNCILMAN, in closing, said the cell degenerations referred to by Dr. Gilchrist were common and perfectly well known. They were found in numerous conditions, but none of them suggested the perfectly definite structure seen in the smallpox organism.

Prof. CALKINS, in closing, said the organism found in smallpox could be traced back through a regular cycle.

The Opsonic Method in Skin Diseases.—Dr. ARTHUR WHITFIELD of London, England, said the term "opsonin" was applied to designate a hypothetical body present in the blood serum. It had not been isolated, but its action had been detected and estimated by Wright and Douglas. The method of opsonic determination consisted of mixing definite volumes of blood serum, bacillary emulsion, and living leucocytes under suitable conditions, and afterwards making stained preparations from the mixture to demonstrate the numbers of ingested bacilli. A comparison of various sêra by this method gave varying results which might be used for the estimation of the individual resistance to the organism in question. The method had been proved to be accurate within the limits of a 5 to 10 per cent. error, which was admitted. The opsonic method might be used for diagnosis, or, in conjunction with the inoculation of bacterial vaccines, for treatment. The diseases of the skin in which the method found a place were the primary and secondary staphylococcic infections and tuberculosis. The opsonic method in boils was always successful, and was the only form of treatment for general furunculosis that was in the slightest degree reliable. In sycosis the method was a valuable one, but must be continued for long periods in proportion to the duration of the disease, and was best combined with *x*-ray epilation. In acne the treatment was uncertain, some results being astonishingly brilliant; others entirely negative. In septic dermatitis and ulcers the treatment was of distinct value as an auxiliary. In Bazin's disease the treatment was somewhat uncertain, but it was often of help. In tuberculous ulceration it was of great value. In lupus vulgaris the treatment alone was too slow and uncertain to be recommended. According to Bulloch, it was a valuable auxiliary in those patients who relapsed after Finsen's treatment, and the speaker said he had found it of value combined with *x*-rays.

Bacterial Inoculation in the Treatment of Suppurative and Tuberculous Diseases of the Skin After the Method of Wright.—By Dr. E. M. VON EBERTS of Montreal, Canada. The author, after a brief review of the technique of opsonic determinations, gave his results with this method of treatment in acne indurata, sycosis, furunculosis, and lupus vulgaris. He stated that in the treatment of tuberculous infections of the skin, the question of autogenous vaccines was at present impracticable, but very encouraging results might be obtained with Koch's new tuberculin (T. R.). Increasing experience showed that the doses originally employed in staphylococcic infections were too large, so that at the present time, instead of 500 millions or more being injected at the initial dose, it had been found advisable to start with 100 or 200 million; or, in a tuberculous case, with 1-2,000 to 1-1,800 m.gm. of T. R. deciding as to the effect and subsequent dosage by the immunity reaction induced in the individual, as interpreted by the opsonic findings. If the negative phase following inoculation was severe or prolonged, the dose should be diminished. Where, on the other hand, the immunizing response was inadequate, *i.e.* where the negative phase was suppressed and the positive phase but slight, the dosage should be increased. The objective and subjective symptoms following inoculation were, to a trained observer, almost as valuable guides as the opsonic findings. Experience taught one that exacerbations in the local symptoms were the harbinger or accompaniment of a depressed opsonic index (negative phase). On the other hand, comparative freedom accompanied the positive phase. This latter phenomenon, no doubt, accounted for the decrease in the amount or severity of pain, which was invariably admitted by patients undergoing tuberculous infections. In old lupus cases the bleaching of the scar was a very striking feature. Constitutional symptoms were rarely met with, and should never develop if the dosage was properly adjusted.

Bacterial Injections in the Treatment of Diseases of the Skin.—By Drs. JAY FRANK SCHAMBERG, NATHANIEL GILDERSLEEVE and HARLAN SHOEMAKER of Philadelphia. In this paper the authors reported 21 cases treated by bacterial injection. This number included 9 case of sycosis vulgaris, 3 of furunculosis, 4 of acne, 2 of acne with sebaceous abscesses, 1 of eczema, 1 of psoriasis, and 1 of lupus erythematosus. Some of these patients had been under treatment only a short time, and were continuing to make progressive improvement. Of the cases of sycosis vulgaris, 1 was entirely cured, 3 were almost well, 1 was greatly improved, 2 were slightly improved, and 2 were not improved. Of the 3 cases of furunculosis, 1 was cured, 1 was almost cured, and 1 was improved. Of the 4 cases of acne, 2 were cured, 1 was not improved, and in 1 the flushing had been relieved. The 2 cases of acne with sebaceous abscesses were decided improved. In the case of eczema with pyogenic lesions, the latter were cured and the eczema rendered amenable to treatment. The case of psoriasis was temporarily improved. The result in the case of lupus erythematosus was still uncertain. Considering the fact that the majority of these cases were rebellious and of long-standing, and that they had resisted approved treatments of all kinds, the results must certainly be regarded as encouraging.

Dr. A. RAVOGLI of Cincinnati said he could confirm what had been claimed for the opsonic method of treatment in sycosis, and his personal experience with it had been very encouraging. With the gonococcic vaccine he had also obtained excellent results in a case of gonorrheal arthitis.

Dr. E. R. LARNED of Detroit said that if we could control the size and frequency of the dosage by the clinical results, then the opsonic method of treatment would come within the reach of many general practitioners; but if it was necessary in each case to compute the opsonic index in order to regulate the size of the dose, and to use autogenic vaccines instead of stock vaccines, then it would be a long time before the method would become of general practical value, and only those cases could be treated which were within easy reach of the laboratory.

Dr. STAFFORD TAYLOR of Liverpool, England, said that some of his cases of sycosis and acne had improved under the use of vaccines prepared according to Wright, but the majority had required *x*-ray treatment before a cure resulted.

Erythema Circinatum Bullosum et Hæmorrhagicum. An Erythematous Eruption, Followed by the Formation of Bullæ and Petechiæ, and by Death.—Dr. WILLIAM T. CORLETT of Cleveland reported a case of this character. The patient was a boy of 12, who received a scalp wound from the ball of a Flobert rifle, for which he was treated at Charity Hospital. No serious manifestations followed, and the wound healed in less than a fortnight. At this time, however, the patient complained of acute pains in the joints, notably in the ankles, which were found to be swollen, and one was slightly erythematous. This was followed by gyrate and ringed patches of erythema, which extended over the whole body. These at first were well defined, of a pinkish tint, with a pinkish fawn-colored central area. Some of the lesions soon assumed a dusky, cyanotic tint, which developed into petechiæ. This was followed by the appearance of bullæ, first seen about the neck, and which within a few days involved, more or less, the entire body. The contents of the bullæ, at first transparent, gradually took on a yellowish color. Later many of the lesions became slightly hemorrhagic. The patient's condition began to fail, and finally, three weeks after the injury and a fortnight after the onset of the disease, he died. Cultures from the purulent and hemorrhagic bullæ gave pure streptococci. The autopsy revealed old fibrinous adhesions about the spleen, and the gross appearance of this organ was found more dense than normal. Small hemorrhagic spots were found near the pyloric end of the stomach. At the cardiac extremity a

small area was found denuded of gastric epithelium. There was no evidence that the gunshot wound had any etiological influence on the disease. The case seemed to demonstrate a connecting link between erythema and purpura.

Dr. Oscar T. Schultz of Cleveland emphasized the fact that in the case reported the general streptococcus infection followed an infection by way of the gunshot wound, rather than the primary involvement of the skin.

Dr. Edward H. Shields of Cincinnati reported a similar case, in which death occurred at the end of the third week.

The Need for Higher Requirements in Examinations in Dermatology and Syphilology by Medical Colleges and Licensing Boards.—By Dr. William F. Breakey of Ann Arbor, Mich. The relative number of patients, clinical and private, suffering from dermal affections, as compared with other special fields of medicine, seemed to furnish a sufficient reason why a general medical education should provide better facilities for the study of dermatology and of syphilis in particular, not alone because of its gravity and often unsuspected presence, but also in view of the awakened public interest in this phase of social life.

Dr. A. Ravogli of Cincinnati said that in all the medical colleges in the State of Ohio at least 64 of the 2,000 hours that made up the yearly college curriculum had to be devoted to dermatology and syphilology. Medical students were already overburdened with work, and he did not think they would ever succeed in compelling the candidates to take a special examination in these branches.

Wednesday, September 11—Third Day.

Dr. Veiel of Cannstatt, Württemberg, and Dr. H. Halopeau of Paris, France, in the Chair.

The first two hours of the session were devoted to the exhibition of patients and formal discussion on the same.

Blastomycosis of the Skin.—By Dr. M. Oppenheim of Vienna, Austria. The first case in Europe conforming with the American cases of this disease (pseudolupus) was observed in Neumann's clinic in Vienna by the writer in 1904. Later he had occasion to observe three others. The clinical picture in the earliest stage was a light, red-stained, swollen lesion, with characteristic pustules. From the latter superficial ulcers with irregular margins arose, which produced superficial scarring. Histologically, there were intra- and subcorneal and intraepithelial abscesses; the rate pegs were increased in size, and the stratum papillare was infiltrated by round cells. In the abscesses and infiltration were found the blastomycetes, singly and grouped, but never abundantly. As the lesions grew older, the picture was similar to lupus verrucosis, with elevations surrounding cicatrized areas, thickening of the nose and lip, excoriations and deep ulcerations with irregular margins and uneven base, covered by thick crusts, sometimes destroying the nostrils and perforating the septum of the nose. From the base of some of the ulcers papillary excrescences soon overgrew the margins and showed points of cornification. Microscopically, there was an overgrowth of epidermis and an infiltration of the corium with round, plasma, and giant cells, even to the subcutis. A few blastomycetes were present. The therapeutic effect of potassium iodide was evident in all four cases.

Systemic Blastomycosis. A Critical Survey and Summary of Nineteen Cases (Four of them Unpublished).—Dr. Frank H. Montgomery and Dr. Oliver S. Ormsby of Chicago, in this paper, stated that about one hundred cases of blastomycosis involving the skin had been recognized, chiefly in Chicago and its vicinity, but also in other parts of the United States, in Canada, in various parts of Europe, in Japan, India, and South America. Of the nineteen cases recorded in this paper, twelve were dead, four were dying, two had recovered, and one had disappeared from observation. All of the cases, with possibly one exception, presented multiple subcutaneous abscesses and nodes, usually indolent in type. With the appearance of the abscesses there had been in all cases a disturbance of the general health. The duration of the disease varied from a few months to two and a half years. Blastomycotic lesions had been demonstrated in practically all of the tissues and organs of the body. The characteristic changes consisted in the presence of nodules or abscesses in the soft tissues, and caries in the bones. The abscesses varied greatly in size. Necrotic areas in bones, containing the organism in abundance, surrounded by leucocytes, giant cells, and other cells peculiar to the granulomata, had been noted and fully described in one case. It was worthy of note that, notwithstanding the presence of extensive suppuration in most of the cases, in two only was amyloid degeneration recognized, and in only one were these changes at all extensive, occurring in the liver, kidneys, adrenals, spleen, the colon, and in various lymph glands. The bacteriology of systemic blastomycosis was identical with that of the cutaneous form of the disease.

Dr. Joseph Zeisler of Chicago said that in view of the fact that there were many dermatologists who still had doubts as to the genuineness of blastomycosis, he wished to state that he had seen many of the cases reported by Drs. Hyde, Montgomery, and Ormsby. He briefly referred to one case of systemic blastomycosis which had been under his personal observation. This patient, after various methods of treatment had been ineffectually employed, went to California, where she recovered spontaneously.

Dr. Thomas C. Gilchrist of Baltimore referred to the similarity between the organism of blastomycosis and that of granuloma coccidioides.

Dr. James Nevins Hyde of Chicago said the fact that they had seen so many cases of blastomycosis in Chicago had been a surprise to them, as well as to their colleagues elsewhere, and he was justified in saying that in the cases reported in the east the symptoms were not so exaggerated or severe as those they saw in Chicago. He therefore had the conviction that the organism which produced the disease was more or less limited to a certain geographical distribution, and that for reasons which he could not explain that particular area was not far distant from Chicago and Indiana. It was there that the organism seemed to flourish as it did nowhere else.

Dr. Howard Morrow of San Francisco said he had had repeated opportunities to compare cultures of blastomycetes with those of the granuloma coccidioides, and he had found that they varied considerably. Both cultures, at the room temperature, had quite a characteristic growth, but the coccidioides grew in the shape of a thick mass, with a sharp edge, whereas the blastomycotic fungus, while it began similar to that of the coccidioides, after a few days developed radiating fibers which spread out and gave the appearance of a halo.

Dr. Douglass W. Montgomery of San Francisco said there was no doubt that there was a marked difference between the two fungi under discussion. In the cases of dermatitis coccidioides, a California disease, the organism in the tissues was a capsule, with spores in it like canister-shot.

Dr. Oliver S. Ormsby of Chicago said that blastomycosis was really a very serious disease, and one that did not belong entirely to the dermatologist.

The Thyroid as a Factor in Urticaria Chronica.—By Dr. M. L. Ravitch of Louisville, Ky. The writer claimed that chronic urticaria should be classified as a curable disease, and in connection with its treatment he made a plea for a more thorough study of thyrotherapy. He firmly believed that in many cases of chronic urticaria, thyroid extract was a specific. He claimed that disorders of the thyroid gland were the cause of many toxemic conditions, and that thyroid extract was an autotoxin; hence its usefulness in toxemic conditions, urticaria chronica in-

cluded. Chronic urticaria was more frequent among women than men, and the fact that functional thyroid disorders were also more common in women led the writer to believe that functional disorders of the thyroid were the cause of chronic urticaria. He regretted that thyrotherapy had been neglected in the treatment of skin diseases, and pointed to the fact that remedies useful in chronic urticaria were also useful in functional disorders of the thyroid gland. Outside of the eruption, the writer claimed, the symptoms of chronic urticaria were almost the same as in thyroid toxemia.

Hydroa Puerorum (Unna). By Dr. Max Haase of Memphis, Tenn., and Dr. Rose Hirschler of Philadelphia, Pa. After reviewing the recent literature on this subject, the authors reported in detail a case of hydroa puerorum seen with Dr. Unna in his clinic at Hamburg, from which a biopsy was made. The histopathological findings in the case were also detailed, and an attempt was made to establish its proper place among the hydroas. In claiming for this disease a place in the nomenclature as a dermatological entity, the authors offered the following conclusions: (1) It was an acute erythematovesicular disease, preceded and accompanied by intense burning and itching. (2) The vesicles coalesced to form bullæ. (3) Involution of lesions without pitting or scarring. (4) The first attack occurred in the first year of life. (5) Recurrence of attacks independent of external influences. (6) Gradual lessening of attacks in extent, intensity, and duration. (7) Spontaneous disappearance at puberty. (8) Unrestricted to any particular lesion. (9) Restricted to male sex. (10) Relatively normal health during attacks. (11) To these might be added the superficial character of the disease, the lesions being confined to the rete.

Dermatitis Coccidioides, with Report of a Case.—By Dr. A. Ravogli of Cincinnati, Ohio. The case was reported under the nomenclature of dermatitis coccidioides because the parasite found in the lesions closely resembled a coccidium. The clinical features of the disease, although related to blastomycetic dermatitis, were somewhat different. The parasite taken directly from the ulcerated surfaces had a long thread of mycelium, but when cultivated on glycerin agar and on blood serum showed only round bodies, with scarcely any mycelium. Its growth was rapid and abundant and its development seemed to be due to endogenous proliferation. The result of the treatment was also different from that obtained in true blastomycosis.

Dr. Douglass W. Montgomery of San Francisco said he could not make out the coccidioides in the sections shown by Dr. Ravogli.

BRITISH MEDICAL ASSOCIATION.

Seventy-fifth Annual Meeting, Held at Exeter, July 27 to August 2, 1907.

Special Report to the Medical Record.

SECTION ON TROPICAL DISEASES.

(Concluded from page 536)

Friday, August 2—Third Day.

Discussion on the Hemoflagellates.—Prof. E. A. Minchin opened the discussion. The zoologist, he said, studied living creatures for their own sake, working at their structure, life history, and habits, with a view to establishing their place in nature and their affinities and relationship with other organisms. The medical man was interested in them only in their relationship to disease. There were perhaps several points at which the spheres of the naturalist and the physician were in contact; certainly one, namely, the study of the life cycle and development of the parasites. This was a study of the utmost importance to the zoologist, since nothing threw more light on the affinities of any creature than its development; it was also of importance to the medical man, because such knowledge gave him a clew to methods of prevention, which were proverbially better than cure. The speaker confined his remarks to an account of the life history of the hemoflagellates, organisms belonging to the class *Flagellata* of the Protozoa, which had as organs of locomotion one or more flagella and which were further characterized by being parasites in the blood of vertebrate animals. Strictly speaking, the genera *Trypanosoma* and *Trypanoplasma* included all the hemoflagellates; that is to say, the flagellates parasitic in blood. But it was impossible in a natural classification to separate these two genera from certain others clearly allied to them comprising forms found parasitic in the digestive tracts of insects such as the genera *Herpetomonas* and *Crithidia*. The majority of the species belonging to these latter genera were found in blood-sucking insects, a circumstance which was highly suspicious, and pointed to their being, perhaps, only stages in the life history of *Trypanosomes*. It was very doubtful whether the peculiar blood parasites known as spirochetes should be included amongst the hemoflagellates or not. Many authorities still supported the older view that these organisms were bacteria belonging to the section *Spirillacea*. The more modern view, first advocated by Schaudinn, was that these organisms were protozoa allied to the hemoflagellates and resembling minute trypanosomes in structure. Schaudinn based this view, however, upon a form which was probably a true trypanosome of small size and not a spirochete. In the spirochetes of human and avian relapsing fever, it had not been possible to demonstrate the characteristic structures of trypanosomes, and their position must be considered at present very doubtful. It was highly probable that the genus trypanosome included forms which, though extremely similar, had two distinct lines of ancestry and descent. They might have inherited from their respective ancestors equally distinct modes of development, so that we should be prepared to find in this genus distinct types of life cycle, and we should not assume that the mode of development found in one species must necessarily be the pattern or model, so to speak, for the whole genus. As the simplest type of life cycle we might take that of the *Herpetomonas* of the common house fly. The parasite lived in the intestine of the fly and became encysted in the mid gut. The cysts passed out of the gut, and, being dropped about in all sorts of places, some of them contaminated the food of other flies, and were accidentally swallowed by them. In this way the cysts passed into the digestive tract of other flies and there germinated, setting free the parasite, which at once commenced to feed and multiply. By this simple direct method the infection passed from one fly to another. We might call this the causal or contaminative method of infection. It was of very common occurrence among protozoan parasites of all classes. In all other known cases, with one exception, the infection was conveyed from one vertebrate host to another by the intermediary of some blood-sucking invertebrate animal. The single exception was the case of dourine, a disease of horses caused by *Trypanosoma equiperdum*; this disease was transmitted by contagion during coitus. The invertebrate animal which transmitted the infection of hemoflagellates differed according to the habitat of the vertebrate host. In aquatic vertebrates such as fish, amphibia, tortoises, etc., it was a leech; in land vertebrates, especially birds or mammals, it was some arthropod, usually a biting fly or mosquito. With regard to the exact method of transmission but little was known. In the first place we must distinguish between what might be termed direct and indirect transmission. In direct transmission the bloodsucker took up the parasite with its food from an infected man or animal and gave it back again to another when next it fed, without the parasite having under-

gone any change or development. The transference of the parasite from one host to another, by this method, was as mechanical and direct as if it had been effected with two stabs of a needle, or by inoculation with a hypodermic syringe. In the trypanosomes of mammals, particularly those carried by tsetse flies, such as the nagana disease of horses and cattle and the sleeping sickness of man, only direct transference of the parasite had been demonstrated with certainty up to the present. In indirect transmission the parasite, after being taken up by the bloodsucker, persisted for some time in the latter and underwent a series of changes, constituting a definite developmental cycle, before being given back again to a new vertebrate host. A well-known example of this type of development was the transmission of the malarial parasite by a mosquito. It was known that the parasite was taken up by the mosquito in a feed of blood from a sick person; that the parasite went through a complicated cycle of development in the mosquito, and that finally the parasite was given back again by the mosquito to another person, passing down its proboscis with the saliva when it punctured the skin in order to draw blood. Hence the transmission of the malaria parasite took place by the indirect method and was of a type which may be termed *inoculative*. Examples of transmission of hemoflagellates by the indirect inoculative method were known to occur in the case of hemoflagellates infesting fish and other aquatic vertebrates; the transference had been worked out by Brumpt, who had shown in the case of the trypanosome of the eel, for instance, that the parasites were taken up by a leech and underwent a definite development in the intestine of this invertebrate, finally passing forward into the proboscis and thence into another eel at a subsequent feed of the leech. Brumpt had further shown that, as in the case of the malaria parasite, a close relationship existed between the parasite and the species of invertebrate that transferred it, and that in any leech except the particular species required, the parasite either did not develop at all or underwent only a part of its development, and in either case no transmission of the infection took place, the whole process being abortive. In the case of the little owl the infection had been worked out by Schaudinn, who had described a very complicated developmental cycle in the digestive tract of the bloodsucker, in this instance a gnat of the genus *Culex*. Indirect transmission of the inoculative type had been much sought for in the trypanosomes of mammals, but had not yet been proved to occur. The trypanosomes had indeed been seen to undergo a certain amount of change in the digestive tract of the invertebrate bloodsucker, but it had not yet been proved that after undergoing developmental changes the parasite was given back again to a new vertebrate host. In the transmission by tsetse flies of nagana and sleeping sickness trypanosomes it was not found possible to demonstrate, either by observation or experiment, any mode of transmission but the direct mechanical one. In carrying on these investigations it had been observed incidentally by all who had been engaged in this work that the tsetse flies caught wild might contain other species of trypanosomes, probably taken up by them from wild animals, and quite distinct from the disease-producing forms. In the case of one of these species the speaker was able to make an observation to which he was inclined to attribute some importance in the transmission of the trypanosomes. At Entebbe, the dusky tsetse fly, *Glossina palpalis*, was commonly found to contain in its digestive tract vast swarms of a trypanosome which Novy had named *T. grayi*. Professor Minchin found that in some flies the parasite occurred in the innermost section of the digestive tract and there became encysted, in a manner very similar to the *Herpetomonas* of the common fly. There could be no doubt whatever that the cysts formed in this way were destined to be cast out with the feces of the fly; the question was, what becomes of them afterwards? It had been stated that in *Herpetomonas* the cysts contaminated the food of other flies and so infected them. The tsetse fly, however, was a bloodsucker and appeared to feed exclusively in this manner; it seemed impossible, therefore, that it could ever infect itself by swallowing accidentally cysts dropped by another fly. The author's suggestion was that the cysts were intended to infect the (as yet unknown) vertebrate host of *T. grayi* by contaminating its food; and that when swallowed accidentally by the vertebrate host the cysts germinated in its intestine, producing probably herpetomonas-like forms, which passed from the intestine into the blood and produced a trypanosome infection. All this was as yet only a suggestion and required proof, but it was put forward as a working hypothesis. The view had been put forward by Léges and others that the ancestors of the hemoflagellates were forms similar to *Herpetomonas* and *Crithidia*, and were parasites of the digestive tracts of insects; and that by the acquisition of bloodsucking habits on the part of these insect hosts they were introduced into the blood of vertebrates and acquired thus a double developmental cycle with change of hosts. The difficulty in the way of this theory was that the invertebrate host was not necessarily an insect, but might belong to very different classes of the animal kingdom; it might be a leech, or an arachnid, a tick. Hence the only feature that could be said to be constant in the life cycle was the possession of a vertebrate host. The speaker suggested that the hemoflagellates were primitively parasites of the digestive tract, not of invertebrate, but of vertebrates. Many flagellates parasitic in the digestive tract of vertebrates, including man, were well known, and recently Léges had described a species of trypanoplasma occurring in the digestive tract of a fish. We might suppose that this hypothetical ancestor of the hemoflagellates lived in the intestine and that its life cycle was similar to that of *Herpetomonas muscæ domesticæ*—i.e. that it formed cysts in the gut which passed out with the feces and were accidentally swallowed with food by new hosts. So far as known, that was the method by which the intestinal flagellates of man or other animals were transmitted from one host to another. The next stage in evolution would have been the penetration of the wall of the intestine by the parasites and their consequent entry into the circulation. When they were once in the blood they found themselves in spaces from which there was no means of escaping by natural channels. Hence, in order to infect new hosts the parasites must do one of two things: (1) They might pass back again into the intestine of the vertebrate host in order to become encysted there and so pass out to the exterior, as before. This was not known to occur in any case, but the possibility existed of this mode of infection occurring, or at least having occurred, and the speaker would call it stage 1 in the evolution of the life cycle. (2) The parasites could be taken up from the blood by a bloodsucking invertebrate of any kind, in the intestine of which they would become parasitic, ultimately producing in this new situation the cysts which they formerly produced in the gut of the vertebrate host. The author would call this stage 2 in the evolution; it was the contaminative type, which he believed to occur in the life cycle of *Trypanosoma grayi*. When a parasitic relationship had become set up between the flagellate and the invertebrate host the third stage of evolution would be that the parasite would penetrate the organs of the invertebrate and reach its proboscis or salivary glands, there producing minute forms which could pass back by inoculation into the vertebrate host. Hence encysted forms would be unnecessary and would cease to be formed, and we should have the inoculative type of infection established. The fourth and final complication of the life cycle would be brought about by the parasites penetrating the ovaries of the invertebrate

host and so passing through two generations of the latter, being given back by the inoculative method by the offspring of the invertebrate which originally took them up. In this way would come about germinative or hereditary infection, well known to occur in *Piroplasma*, but not known with certainty in hemoflagellates. Finally, a few words about the herpetomonas of the house fly. The fact that this parasite had no vertebrate host might be regarded as supporting the view that the hemoflagellates were originally parasites of the gut of invertebrates. But it has been pointed out by Prowazek that the house fly was probably descended from bloodsucking ancestors and was to be regarded as a form which originally had, but had given up, the bloodsucking habit. Prowazek suggested that its herpetomonas parasite was acquired by its bloodsucking ancestors and was originally a form with an alternation of hosts, vertebrate and invertebrate. When the fly ceased to suck blood, however, the flagellate remained as a parasite of the fly alone and was to be regarded as a form stranded and left behind, as it were, by changes in its life conditions over which it had no control, like marine animals left behind in inland lakes by elevation of the land. Hence herpetomonas did not dispose of the suggestion that the ancestral hemoflagellate was a parasite of the vertebrate intestine. From a consideration of the evolution of these parasites there was the possibility of the existence of at least four distinct types of life cycle in hemoflagellates.

Dr. Louis W. Sambon maintained that *Glossina palpalis* played the part of a true alternative host and was not merely a mechanical carrier of the parasite of sleeping sickness. Direct mechanical transmission might occur under certain conditions, and indeed it had been brought about artificially both in sleeping sickness and nagana by means of tsetse flies and other flies, but certainly this could not be the usual mode of transmission under natural conditions. The malaria parasites might be transmitted indefinitely in their schizogonic stage by the direct inoculation of infected blood, but in nature they were propagated by specific mosquitos, which acted as their necessary definitive hosts. The strict limitation of both sleeping sickness and nagana to the peculiar stations of their specific carriers proved that the transmission could not be as simple as suggested by Colonel Bruce and Professor Minchin. Brumpt and others had proved that the trypanosomes of fish were transmitted by the indirect inoculative method and that they underwent a definite development in the body of the leeches which subserved them as definitive hosts. Why, then, should we be so reluctant to accept a similar mode of transmission for the trypanosomes of mammals and birds? We had ample evidence to show that the trypanosomes of mammals underwent a sexual cycle within the body of their respective invertebrate hosts. Dr. Sambon had pointed out some years ago that the sporonts of *Trypanosoma gambiense* might present sexual differentiation in the blood of long-standing cases. Koch, Prowazek, and others had shown that trypanosomes multiplied rapidly and acquired marked sexual differentiation within the gut of their invertebrate hosts. Koch had found numerous trypanosomes and no traces of blood in the clear liquid contained in the bulb of the proboscis of *Glossina fusca* infected with the nagana trypanosome. These forms were ready to be inoculated into a fresh vertebrate host and showed that the trypanosomes did not leave the body of the fly by way of the intestine, as suggested by Prof. Minchin. Koch, Bruce, Minchin, and others had invariably failed in reproducing the disease by inoculating the blood from the stomach of the fly teeming with vigorously active trypanosomes. This proved that the forms in the gut of the fly were gametes that must undergo a special development and were not able to reproduce any longer by schizogony. Dr. Sambon said he believed that the trypanosomes of both sleeping sickness and nagana were transmitted by hereditary infection. The peculiar mode of development of the tsetse flies suggested this mode of transmission.

Sir Patrick Manson, K.C.G.M., F.R.S., said the phylogenesis of parasites requiring two hosts dated from ancestors which in the history of evolution antedated the differentiation of the arthropodes from the vertebrates. Parasites evolved *pari passu* with their hosts and when these hosts diverged into species and genera these parasites adapted themselves to the altered conditions. Some eight or ten years ago he undertook to write a book on tropical medicine. At first the task was relatively easy, but in the progress of time and in consequence of the advances of tropical medicine the number of organisms, especially of those haunting the blood, with which he had to deal, became in subsequent editions so great that the work was almost overwhelming. In his trouble he asked Dr. Sambon to help him in arranging the blood protozoa in a way that might help and guide the medical man. The result was the following classification, which was based not on external organs such as flagella, but in the case of families on the behavior of the oökinete in the formation of sporozoites, and in the case of genera on the size and shape of the gametes.

CLASSIFICATION OF BLOOD PROTOZOA.

HÆMOPROTOZOA—Sambon, 1906.

- Oökinete
  - Encysts
    - Produces sporozoites in secondary capsules or spore bags..... — Hæmogregarinidæ, one genus, *Hæmogregarina*
    - Produces naked sporozoites ..... — Plasmodidæ, two genera: *Plasmodium*; *Laverania*
  - Remains free
    - Elongates and breaks up into numerous sporozoites ..... — Spirochaudinnidæ, three genera: *Leucocytozoon*; *Spirochaudinnia*; *Treponema*
    - Divides by longitudinal fission into two equal forms which divide again and again until minimal forms are reached, which represent sporozoites..... — Hæmoproteidæ, two sub-families:
      - Hæmoproteinæ, 1 genus, *Hæmoproteus*
      - Trypanosominæ, 4 genera: *Babesia*; *Leishmania*; *Trypanosoma*; *Trypanoplasma*

Development of Piroplasma Canis in the Tick.—Captain S. R. Christopher, I.M.S., read this paper. The development took place in *Rhipicephalus sanguineus* (Latreille), a common tick of dogs in India. It might

take place both in the adult tick and in the nymph. When it took place in the adult the infection was transmitted hereditarily; when in the nymph it could be transmitted by the adult. After reaching the gut of the adult tick the parasites enlarged and assumed a round or oval shape. Before reaching their full size they often showed irregularities, but the long processes described by Koch did not seem a necessary part of development. After attaining from 4 to 5 in diameter an achromatic line appeared, which divided the parasite approximately into two halves, one containing the chromatin mass and the other no chromatin. The two halves eventually separated, except at one point, and the portion without chromatin swung round to become the tail of a club-shaped body, the half with chromatin forming the anterior portion. The club-shaped body developed a peculiar apparatus at the anterior end and migrated to the ovary. Here it penetrated an ovum, swelled up and became a round body which might be called a "zygote" because of analogy with the malaria parasite. The zygote quickly underwent a great increase in size, reaching eventually as much as 25 . Then it broke up into a number of bodies termed "sporoblasts," which were found disseminated in the tissues of the larva. Finally, the sporoblasts divided to form bodies very closely resembling the blood forms. These being found collected in the salivary glands of the nymphs were termed "sporozoites." When development took place in the nymph the club-shaped bodies left the gut and penetrated the tissues, embedding themselves in the protoplasm of the embryonic tissue cells, which were already beginning to form the future adult. Many of these invaded cells later formed the salivary gland, a structure which occupied a large portion of the body of the infected tick. The sporozoites thus found themselves *in situ*. Many parasites, however, invaded embryonic cells which did not eventually become salivary tissue, and in that case the probability was that the sporozoites reached the salivary gland by their own movements.

Bilharzia (Schistosomum) Disease in Cyprus.—Dr. G. A. Williamson read this paper. He said that at the Manchester meeting of the British Medical Association in July, 1902, he had reported a case of bilharziosis from Cyprus on account of its interest from the point of view of geographical distribution. The case occurred in a policeman from the village of Morphou in the northwest of Cyprus. In March, 1906, having met with three further cases in persons from Morphou, he obtained a day's leave and devoted it to visiting the village, with the idea of investigating as fully as the very short time allowed the circumstances of its prevalence there. He found that the villagers were perfectly well acquainted with the disease, which they considered an inflammation of the kidneys due to exposure to the cold water in the river bed at Syrianokhori, a village two miles away, in those who went there to fish. Four persons came for examination, all being Morphou villagers, and all stating that at one time or other they had had hematuria. In the urine of three of these Schistosomum ova and blood corpuscles were found on microscopical examination. On going to the Syrianokhori school and examining the children there, the following result was obtained: Out of eight pupils present the urine of seven was examined and ova and blood were found in the urine of five children. In Morphou village the inhabitants stated that infection occurred solely among those frequenting Syrianokhori to bathe, wade, fish, water animals, or otherwise expose their skin to the water in the river bed. No case could be found among the females of either village, they not frequenting the river in the same way as the males did. In all cases examined the ova had the terminal spine of *Schistosomum hæmatobium*, and inquiry did not suggest the presence of rectal symptoms that might be caused by *Schistosomum mansoni*.

Books Received

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

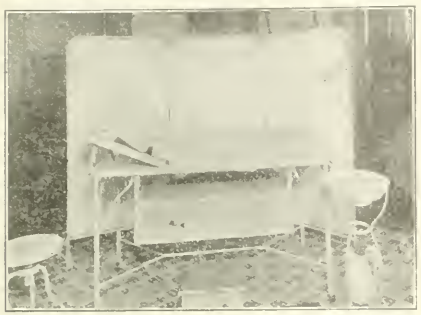
New Instruments.

A NEW TABLE FOR RECTAL WORK.

By CHARLES ALBERT SEWALL, M.D.

LOS ANGELES, CAL.

THIS table was born of necessity, was invented by myself, and has been used in about 5,000 treatments and operations on the rectum. The following are its advantages: The large drawers, with two compartments each, hide all instruments, cotton, gauze, bandages, medicines, and appliances out of sight, and at the same time they are exceedingly handy—within



reach at all times. The drawers can remain open when the patient is on the table, or closed if necessary while he is in position. My method is to put the patient in the Sims position, and as soon as need be to open the drawers, proceed with the operation, and to close them again, when he can step down and off the table. It is practically aseptic, or can be made so easily. Its appearance is good, being made of white enameled steel. The headpiece is easily lowered or elevated. The large rubber casters render it easily movable to any part of the room, so that the light can readily penetrate the speculum when *in situ*. It is practically indestructible.

507 DOUGLAS BUILDING

The Thymus Gland.—T. Gillman Moorhead, after describing the structure of this gland, states that according to many writers degeneration of the intimate structure of the organ, without loss of weight, occurs before puberty, but he adds that nothing absolutely definite is yet known except that, as a rule, there is a gradual increase of the interstitial connective tissue. Exophthalmos caused by the intravenous injections of thymic extracts has lately been shown to be produced by retroorbital hemorrhages, and is probably in no way specific, being caused by the nucleoproteids present. A study of recent work leads to the conclusion that this gland must exert some influence upon nutrition and also upon hemopoiesis. Pathology supports this view. Thus, in acromegaly, a persistent and enlarged thymus is the rule, and, apart from blood diseases, it is found that the thymus enlarges and shows evidence of active cell proliferation and division in most acute conditions attending leucocytosis. It is probable that its blood-forming function is entirely confined to the white cells. The writer believes from his own experiments, and from the study of those of Hexner, that although it is now recognized that cytotoxin sera are more difficult to produce, and are less specific than was at first thought, it must be admitted that the importance of the hemopoietic and other functions of the thymus in extrauterine life is not very great. The pathological changes in which the thymus is subject are very numerous.—*The Practitioner.*

THE SPECIFIC ACTION OF RADIUM AS A UNIQUE FORCE IN THERAPEUTICS.*

By ROBERT ABBE, M.D.,
NEW YORK.

In recounting the diseased conditions of the body in which we see favorable restorative power from radium, I do not invite criticism from those who may say that the same effects can be produced by caustics, Röntgen rays, dietetics, local medication, or electricity. I wish briefly to present facts to show that radium acts entirely unlike these, and to clear the air of some prevailing exaggeration and doubts.

Butlin recently said "there are two kinds of evidence: that which satisfies the inquirer who wishes to believe, and that which is required by the skeptic." If both these could follow the interesting series of results which men who have been able to use this remedy have seen, argument would be simple.

The inefficiency of word description or photography in delineating surgical growths, led me long since to keep records by plaster-of-paris casts, where possible, to enable me more accurately to compare by measurement and appearance before and during the study of radium effects.

A few demonstrations of this are more quickly convincing than words or photographs. As a basis for argument, therefore, I present to your notice a small group of casts chosen from hundreds which I have made.

As a typical epithelial carcinoma, observe this round, raised growth on one side of the forehead. It is 2 cm. in diameter by a half cm. in height. Strong radium (60 mgr. pure radium bromide) sealed in a glass tube, pressed against the growth for one hour, produced a prompt disappearance with only a shallow pink cicatrix.

*Read before the Sixth International Dermatological Congress, New York City, September 12, 1907.

Another of the same size on one side of the nose growing worse for two years, in an elderly lady, and showing fungus ulceration, disappeared in four weeks after one application of one hour. The accompanying cast shows the almost invisible shallow cicatrix. This has remained cured for three years. Scores of such cases have yielded similar results under radium treatment. Many of these casts have been modeled before and after treatment and show the specific action of this agent, with almost infallible results.

Observe this severe case of epithelial cancer of the nostril, septum, and upper lip, in a lady of 70 years. It had become distressing to herself and friends. When she was referred to me her age and delicate physique, as well as her dread of disfiguring operation, led me to try radium. I laid upon the diseased part Curie radium 15cgr. 300,000, and 10 mgr. 1,000,000, this would represent about the strength of 20 mgr. of the present standard pure German radium bromide. This was repeated for one hour on ten successive days. A slight reaction was then noticed, and treatment stopped. At two weeks the edges were much flatter and contracting, while discharge had ceased and the florid granulation changed to a gray surface, exuding a little thin lymph. In five weeks the entire sore had healed, and only a thin small cicatrix remained. These three stages are veritably shown in the accompanying colored casts (Fig. 1). Two years have gone by and the patient remains cured with a perfect smooth, small cicatrix.

The same type of disfiguring cancer is shown in another cast, one nostril and cheek being diseased. This patient was sent to me by Prof. Weir to see if a disagreeable plastic operation could be avoided. Three short séances, total thirty-five minutes, were given with the strongest specimens (amounting to twelve times the working unit of 10 mgr. pure). In two days it already had begun to retrograde, and in three weeks was entirely and permanently healed.

On the same day, nearly two years ago, another

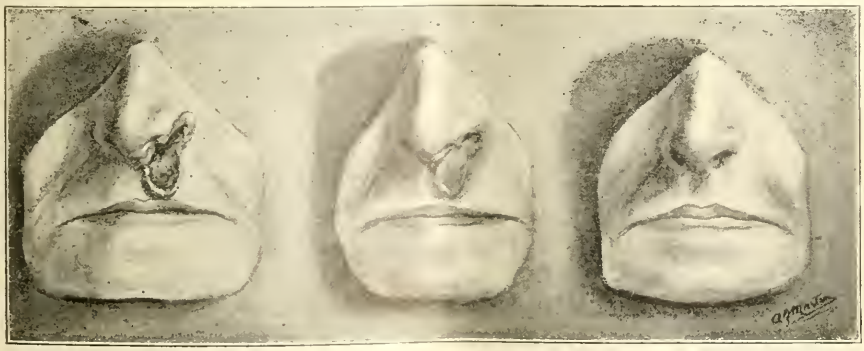

FIG. 1.—Epithelioma of the nose and upper lip, showing dimi[illegible]en at the end of two weeks, and disappearance at the end of five weeks.

man was referred from the same surgeon, for a similar growth which had involved one-third of the upper eyelid. Three five-minute seances with one cell of pure German radium bromide, 10 mgr. (working unit), permanently cured this man in two weeks.

In such cases I protect the eye by thin sheet lead, shaped like a spoon handle, covered by gutta-percha tissue, and slipped under the cocainized eyelid, between which and the radium the diseased part is compressed.

I show you also many other colored casts, indicating the condition, treatment, and result. A large proportion of these are situated upon the face, neck, and ears. These are not only favorite sites, but offend by their disfigurement, and tax the ingenuity of the surgeon to remove by a plastic operation adequate to prevent recurrence.

Most of the grave cases were subjected to critical microscopical study before treatment, and so uni-

Fig. 2.—Showing the [illegible] of [illegible] radium in [illegible].

formly found to be epithelial carcinoma that in minor cases I have trusted clinical appearances, which to me, after thirty years of surgical work, seem worthy of confidence.

The accompanying card (Fig. 2) shows a face, on which I have charted the presence of seventy-seven cases of epithelioma (or lupus that has in parts become epithelomatous) on seventy patients.

This represents a selected typical series, but by no means all, which I have treated by radium for this particular disease. Numbers of these existed for years as keratoses before becoming epithelomata. The ordinary senile keratosis has not been included among them, but forms another [illegible] interesting series. It can be made to disappear always in ten days by one application of twenty minutes of the working unit of radium.

Of the epithelomata charted above I may say that I have yet to lose one case which did not show retrograde [illegible] to the eye. In some of these, however, which had involved deeper layers than the cutaneous, the invasion would sometimes [illegible] ahead of the tissue treated, as, for example, in the orbit where the eyelid had first been diseased, and a mass had grown into the underlying cellular and fatty tissue of the orbit. One would uniformly see a superficial cure and a partial deep reduction. Then, after some weeks there followed a progressive invasion beyond where it seemed wise, or possible, to treat it on account of the proximity of the eyeball. In such cases, therefore, I have treated the case up to this point, and then thoroughly removed the diseased orbital contents.

Epithelioma of the eyelid, when confined to the cutaneous, mucous or glandular structures, seems to be controlled and cured as by a specific. No surgical agent has yet been found so efficient. Even small specimens of 1 milligram of strongest German radium bromide have shown their beneficent action.

As a further note preliminary to better understanding of the unique action of radium, let me recall its value in treating warts. The curative action is perfect in every case, no matter how inaccessible, even under the finger nails, or how large or ancient. A radium specimen sealed in a glass tube will always cure by contact. Even on the soles of the feet where painful callus had been found to have verrucous base, one application of radium has produced prompt cure in three cases.

In melanotic moles—either congenital, hypertrophic, or hairy—the action of radium is almost specific, and with this singular coincident action, namely, that where the dosage is graduated correctly the hypertrophic pigmented tissue atrophies and leaves normal appearing skin. Even in the pigmented skin of a black man I found pink skin areas defined the points of contact with my radium tubes. I have thought it might have selective action for pigment layer cells, and may be used in melanotic growths; hence, I have used it in superficial brown moles, coal black melanotic moles, recurrent nodules of melanotic sarcoma, melanotic epithelioma (primary), and on thick-skinned, hairy, pigmented moles. The result is invariable—the growth and pigmentation uniformly retrograde.

To illustrate, let me cite a case of pigmented hairy mole of the face. Large, hairy, pigmented mole on thick brown skin, covered with hair like a mouse skin, in which were a large number of longer hairs 1 to 1½ cm. long. Approaching this novel condition with caution, I began in June, 1906, with the strongest tube, 60 mgr., pure radium, pressing it on various parts for half an hour at a time. On three occasions during two weeks I applied it in all two and a half hours. On the following week a sharp reaction occurred with blistering and epilation. Watching the results of each treatment, I proceeded with such slowness that during nine months I made thirteen treatments, a total of eleven hours (nine hours of 60 mgr. tube and two hours of 10 mgr. cell). This would represent, therefore, fifty-six hours if I had used only a 10 mgr. tube.

The result is a perfect cure, with reduction of the thick pigmented skin to normal quality without vestige of a hair. At one stage a large part was normal, except for a thin coffee-colored stain. Assuming that some pigmented cells were undertreated, I made short applications of radium, and the color entirely faded. Had I to treat the case again I would apply to the entire surface my strongest radium tube, 60 mgr., for one hour each week—not pressing it longer than five minutes on any one spot. I believe eight séances of one hour each would produce a cure—and without a scar.

Let us emphasize the retrograde change that takes place in the pigment cells, the hair bulbs and cutaneous gland structure. In other words, radium

has changed a patch of thick skin resembling that of a hairy animal to human skin.

I ask attention to another case demonstrating radium's unique power. The casts here shown (Fig. 3) accurately depict a tumor of the lower lid in a middle-aged man, growing more than a year, microscopically a small-celled sarcoma which had progressively grown in spite of careful Roentgen-ray treatment. Four times I laid upon it some little sealed tubes of radium (total strength 20 mgr. R. Br.) for an hour each time—then waited. In two weeks the retrograde began. In four, as the cast shows, it had undergone rapid decline, and in eight weeks it was gone. The patient presents himself for you to see that after two and a half years he remains absolutely well without recurrence, and that you cannot distinguish upon which eye the tumor was situated.

Fig. 3.—Sarcoma of the lower eyelid, showing condition at the beginning of treatment at the end of two weeks, at the end of four weeks, and disappearance at the end of eight weeks.

In the spindle-celled sarcomas I have observed an arrest, but not a decline of the tumor, and will at present say nothing more of them.

But in a group of so-called giant-celled sarcomata, five in number, I have been able to demonstrate what seems to me to be a distinct specific action.

I reported in 1904 the case of a lad in whose lower jaw the bone was practically destroyed at one part and replaced by a soft purple growth—sarcoma rich in myelo placques.* Under radium stimulation this growth was rapidly reduced in bulk, developed ossific points throughout, and finally became solid with new bone. The boy has had no treatment for three and a half years, and he has now a solid jaw bone.

In a similar condition in a case referred to me by Prof. E. G. Janeway, an elderly lady had a fracture of the lower jaw and a tumor had developed at its site. Several treatments were given with rapid retrograde of the tumor, and fine bony union resulted.

In a lady of thirty years, prolific development of soft giant-cell growth of both upper jaws and the lower right jaw has been kept in check by radium application during two years. On every reappearance of the purple growth it promptly shrinks after one or two applications.

In a small Italian lad the entire hard palate was replaced by a soft giant-celled sarcoma; it expanded the upper jaw and was not less than 3 cm. in depth. Into two points in the mass where tissue was removed for microscopical study, the strongest radium tube (60 mgr. R. Br.) was inserted for one hour on two occasions. Rapid atrophy of the whole central mass, and ossification of the remainder, followed in a few weeks—and the apparent cure continues one year after.

In a fifth case a bleeding growth began between the incisor and canine tooth—microscopically shown to contain giant cells. Two applications of radium, 20 mgr. R. Br., total one-half hour, gave prompt arrest of hemorrhage and shrinkage of the growth.

*See Medical Record, August 27, 1904.

The force issuing from an hermetically sealed tube of radium consists of certain obscure radiations, to which the name beta and gamma rays have been applied, the former carrying a charge of negative electricity, the latter being without apparent electric charge. (The alpha rays carry a positive charge, but have such little penetrating power that they cannot escape through the glass.)

The beta and gamma rays are indistinguishable in their physical character from, on one hand, the electrons thrown off by the negative disk of the Roentgen tube, and, on the other, the rays emanating from the tube (Lodge).

It is easy to distinguish two methods of radium action. One, the specific retrograding effect on neoplasms, whose essential substance is an erratic overgrowth of epithelial, embryonal, or glandular structures. (The latter is seen in parotid or thyroid tumors, where extraordinary changes are occasionally produced by radium, though its precise limitations cannot yet be assigned.)

The other effect is seen in the occlusive blockade of highly vascular tumors by irritant action, as in nævi and large angiomata.

That its power does not reside alone in producing local inflammation is shown by its effect on dry seeds, whose life force is changed by exposure to it, so that growth is retarded after planting, in proportion to the time of exposure.

Also in animal life, as illustrated in meal worms, where radium so represses them that they go on living as meal worms, "veritable Methuselas," as it has been said, while their sisters and brothers, unradiumized, progress for generations, completing several cycles of beetles, eggs, meal worms, etc.

Of radium action on bacteria, it is enough to show two culture plates, upon whose central part strongest radium has been playing through sterile paper for fifteen hours. The colon bacillus and *Staphylococcus aureus* growth was checked thereby only in the immediate vicinity of the radium, after this very long exposure. In one a lead strip was interposed and growth occurred beneath it.

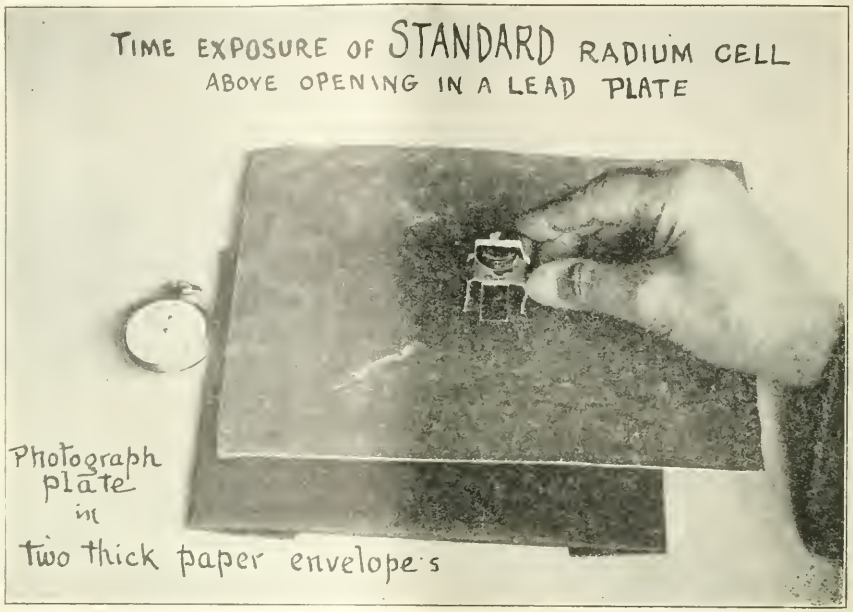
The time needed to destroy bacterial life in these cultures makes it improbable that the good action of radium can be considered bactericidal in malignant growths (even if these had been proved to be of bacterial origin), because that length of exposure would destroy all living tissue at the site of application. Practically the best results are seen when a tenth of this force is used and no necrosis of tissue follows. It is improbable, therefore, that its value is due in any large degree to its bactericidal power.

I invite your attention one moment to a very practical point, a simple and accurate method of measuring the power of radium specimens. Investigators have used extremely variable strengths and amounts of this precious mineral. It is fair to say that moderately strong specimens may be effectually used, but that very weak ones show uncertain results.

Hence, a standard may well be adopted, and must be put at the present time as 10 mgr. of the German pure radium bromide strength denominated 1,800,000.* Let us call this the "working unit."

Inasmuch as innumerable variations from this, both in weakness and quantity, are in use, we must

velopes and mark across the paper two series of squares, writing in each the numbers 5, 10, 15, 20, 30, 40, 50, 60; cover the surface with sheet lead in which a corresponding square is cut. Place this over the first square and suspend above it the standard 10 mgr. R. Br. held at a fixed distance by a bent



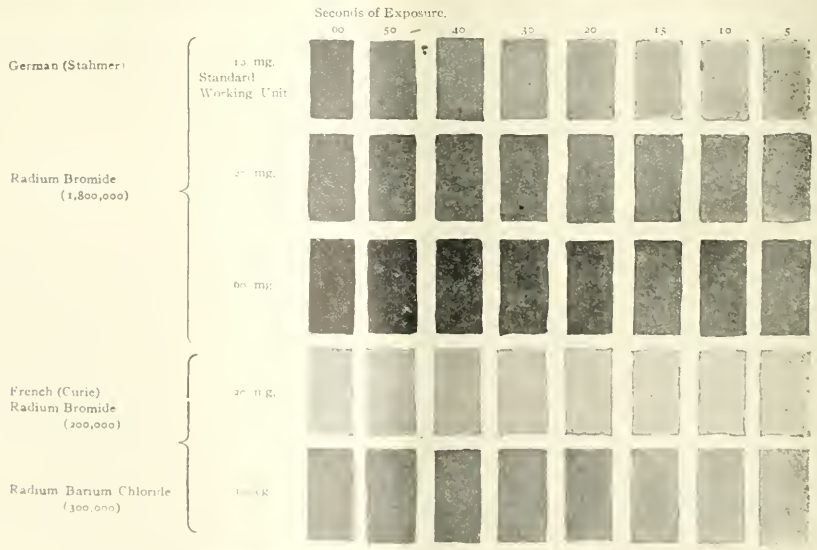


FIG. 4 [illegible] test mate of the working value of radium specimens.

have a fair gauge—and I offer the photograph plate as the easiest and most acuracte test. (Fig. 4.)

I have graphically shown my method of determining the working value of an unknown specimen. Enclose a sensitive dry plate in two black paper en-

piece of lead. With a stop watch in hand, expose it five seconds, move the open lead to the second square, expose 10 seconds, and so on for all. Repeat these exposures on the second series of squares using the unknown specimen of radium for the same exact times as the standard. When the photograph

*Obtainable from Hugo Lieber, 1 Platt street, New York.

plate is developed one sees two series of squares delicately shaded exactly in proportion to the time of exposure.

Observe that a shade of standard five-second exposure is identical with that of the unknown specimen of thirty seconds. We have accurate value, then, for the working force of the unknown, which will require six times the length of exposure to a tumor as the standard.

Having established the working value of a specimen of radium one may produce the results which one sees from the working unit of 10 mgr. R. Br. (1,800,000) as follows:

1. If this be placed upon the skin for ten minutes nothing will be seen for a week. Then a pink-red spot appears, with itching and burning. After two weeks it has gone.

2. Exposure of 30 minutes. Burning, itching, and redness occur in three days, are more severe, and last two weeks. If an epithelial growth has been treated, its retrograde begins about the tenth day. In previously painful tumors the pain usually stops.

3. If an ulcerated surface be treated, or a strong radium tube be inserted in a wound for twenty-four hours, there will result a specific toxemia in many cases. The symptoms will be headache, chill, general aching, coated tongue, fever up to from 103° to 106° F., and an occasional rash like that of scarlatina.

In six cases that were perhaps overtreated, I have seen a spreading rash resembling erysipelas starting at the diseased ulcer, and subsiding after two or three weeks.

In all cases of severe reaction the sequel has been favorable. In two, however (one cancer of the tonsil and one of the tongue), I thought the patient not as well for a time afterward. But reviewing all, I can definitely state that I have never seen harm follow the use of strongest radium. On the other hand the curative effect of severe reaction healed a large, deep angioma of the parotid, after grave toxic symptoms, with temperature 106° F.

At first I thought the toxemia might be favorable, owing to absorption into the lymphatics of a self-generated toxin (or antitoxin) along the line of preceding disease absorption. This hypothesis was disproved by two facts; first, that subsequent examination of axillary glands removed from a patient with a mammary scirrhus, who had had a lively toxic reaction, showed the disease still present in them, while the breast tumor had atrophied. Second, that the same toxemia occurred while treating a case of goiter and one of parotid tumor, in which a radium tube had been inserted with lively effect. Here was no chance for antitoxin generated from malignant growth.

I may say that my glass tubes are always cleansed and immersed in 95 per cent. carbolic acid, followed by alcohol—both after and before using—so that no infective toxemia would be likely to occur. I conclude, therefore, that fever is due to cell necrosis close to the strong radium tube, and not from liberation of a toxin.

In what does the beneficent action of radium reside? This question, with many others, still awaits solution.

We know only that we have a subtle force, which, as far as we discern, is a stream of rays charged with negative electricity with intense penetrative power, capable of traversing stone, human flesh, or solid steel with facility, which plays upon the vital cells (animal or vegetable) and alters their rate of growth, or kills them altogether.

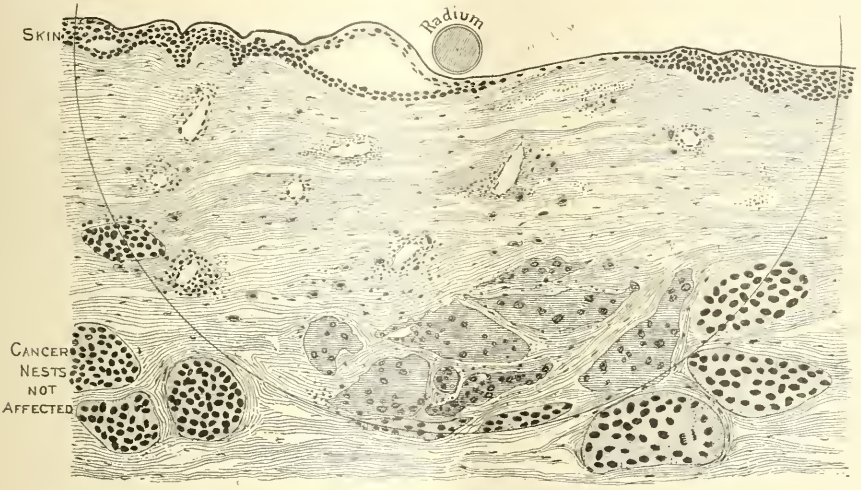

Fig. 5.—Recurrent subcutaneous nodule degenerating under one radium application; showing the sphere of influence; the dead cancer nests are indicated by horizontal hatching.

What the vital spark is in a living thing no one knows. It has been surmised that life itself may only be an embodiment of electric force. It has been supposed by some that a living cell continues its normal career owing to a balance established within it between positive and negative electric force, and that an aggregate mass of cells in the body, such as constitutes a tumor, may result from their erratic growth owing to a loss of balance of electric equilibrium. May it not be reasonable to suppose that a mild application of radium emitting its distinctive rays is thereby capable of restoring the electric equilibrium, while on the other hand a prolonged and intense application carries the balance to a destructive termination?

Consider for a moment that remarkable case you have seen of the tumor of the eyelid. It had displaced the normal skin and mucous membrane, and grown in bulk many times the size of tissues that had been lost in it. There was no semblance of an eyelid in the mass whose tuberous growth rose in

heaped up masses on the skin, and within, and on the edge.

A cross section would have shown no vestige of former tissues which were destroyed or lost in the mass. Yet, when retrograde was finished under radium action, behold the normal skin structure, the normal edge of the eyelid, normal mucous membrane, normal glands, and eyelashes! The original cells were not destroyed. There was a reassembling out of the conglomerate diseased mass. Whence, then, came the diseased cells? This can be answered only by the assumption that an intercellular invisible and ultramicroscopic system of particles had existed with a life of their own, constituting a network holding the visible cells together. This system, then, had itself taken on an erratic growth and become a sarcoma mass, engulfing the regular occupants of the ground.

Conclusions.—Radium ranks, not with caustics, cautery, antiseptics, or medication, but with specifics.

This does not mean a "specific" for cancer, in the popular sense, but for erratic cell growths constituting some types of tumor tissue in the earlier stage of invasion, or of moderate development.

Details of the methods of using it have not yet been fully worked out. The dosage, so to speak, or time of exposure necessary for curative action, is as yet empirical.

Some apparent cures of small epitheliomas or sarcomas have endured already more than three years.

A photographic plate provides a good test, to show the working force of an unknown specimen, in comparison with one of standard strength.

It is not entirely a mysterious force—but, in part at least, is an electric discharge, essentially of negative elements. Hence, as far as it is possible to say, it suggests a theory of its action, in that it may supply an element of electric force vital to normal and orderly growth, the loss of which may have caused a disorderly cell growth which, in the aggregate, constitutes tumor masses.

It is supplementary to Roentgen rays, and, in some cases, is efficient where they fail.

The overaction of strong radium is destructive and vitiates the benefit of moderate use.

The best results have followed one hour's exhibition of the working unit (10 mgr. R. Br.) on small growths, and three to four hours on larger ones, with an interval of one month for study of the effect.

Ischemia of the parts during treatment greatly enhances its action.

Pigmented moles, melanotic growths, and giant-cell sarcoma, like epitheliomata of the eyelids, face, and body, are particularly susceptible to its curative action—as a specific agent. But its value in nevoid and angiomatous tumors is due to its irritant action, producing obliterating endarteritis and fibroid changes.

A Bacillus in General Paralysis.—A. M. Robertson states that he has found a bacillus (Muirhead's diphtheroid) in the blood of persons suffering from general paralysis, adding observations on the *Bacillus paralyticans*. The primary observations were restricted to cultures made from the blood and cerebrospinal fluid of living general paralytics. The mucous surfaces were avoided, owing to the recognized occurrence of diphtheroids in those regions in other conditions, and post-mortem results were treated as of secondary importance, owing to the tendency to ante mortem invasion by microorganisms, and the rapid putrescence of those dying from general paralysis. The positive result of these researches was the finding in the blood of a bacillus of the xerosis group of diphtheroids differing from *B paralyticans*.—*British Medical Journal.*

PRACTICAL VENEREAL PROPHYLAXIS.*

By DENSLOW LEWIS M.D.,

CHICAGO.

THE DELEGATE OF THE SECTION ON HYGIENE AND SANITARY SCIENCE OF THE AMERICAN MEDICAL ASSOCIATION.

During the past few years the attitude of the medical profession towards venereal prophylaxis has undergone a marked change. To-day the sentiment may be said to be almost unanimous in favor of publicity. The medical press, which only a few years ago refused, in some well-known instances, to publish any reference to sexual hygiene or prostitution, now takes note of all attempts at prophylaxis, and even advises in editorial comment methods not long ago tabooed or, what is worse, totally ignored.

Medical societies have also taken action in this regard, notably the State Medical Societies of Washington and Michigan. In the latter State a standing committee was created two years ago who shall act as "the exponent and executive arm of the society in dealing with this important matter of venereal diseases."[1] The Washington State Medical Association appointed a committee on venereal prophylaxis in 1903. Two years ago the report of the committee shows, in answer to an inquiry regarding methods of instruction in use in various clinics throughout Canada and the United States, that thirty-two give verbal instruction only, and two issue pamphlets on venereal diseases. The society suggests a permanent committee on venereal prophylaxis to compile and issue proper pamphlets to be distributed by the profession. The committee of the Washington State Society, under the able leadership of Dr. G. S. Peterkin of Seattle, has prepared five pamphlets which consider the frequency and economic dangers of venereal diseases, the facts concerning gonorrhea or clap, rules for persons having gonorrhea or clap, together with rules to prevent complications and aid cure, facts concerning syphilis or pox, and instructions for persons having syphilis or pox. Each pamphlet is written in plain language, can be read in three minutes, and is of convenient size to be carried in an envelope or pocketbook.[2]

In 1901 the American Medical Association, as is generally known, effected a definite organization. Prior to that time attempts to interest the profession in venereal prophylaxis by favoring educational methods were, to say the least, unsuccessful. Valentine's experience[3] and my own on two occasions illustrate the former intolerance of professional opinion, even to the mention of such "filthy" subjects.[4] One object of such organization is said to be "to federate the medical profession of the United States for the purpose of enlightening and directing public opinion in regard to the broad problems of State medicine."[5] At the Saratoga meeting in 1902 the oration on "State Medicine" said: "Compulsory examination of prostitutes is another necessity for the purpose of preventing the spread of venereal diseases. It is said that either the city of New York or Chicago contains at the present day venereal infection sufficient to contaminate the male population of the United States in a very short space of time. We do not want legalized prostitution as it exists in European countries. I do not believe in authorizing houses of debauchery and making of prostitution a regular profession. The State has no right to regulate prostitution. I am proud of my country, which is fortunately free from the incubus of State-regulated vice. All that is desired is a State law for municipal governments to keep a register of all women

*Presented at the fifty-seventh annual meeting of the Illinois State Medical Society, held in Rockford, May 21 to 23, 1907.

known or suspected of prostitution and that such women shall be liable at any time to be called in for examination. But no certificates should be issued to them as to their healthy or unhealthy condition, for such a certificate would simply encourage the vice. However, if found affected with a venereal disease, they should be sent to a detention hospital or sanitarium and should be detained there until cured." The Massachusetts law is favored, which advocates that "a suitable hospital or sanitarium devoted to diseases peculiar to prostitutes should be established in each and every city, with the power to place and keep there all women so diseased until cured. The hospital should not be intended as a prison, for such is directly contrary to reformation. Liberal arrangements as a hospital would afford no encouragement to vice, and would certainly help wonderfully to eradicate the evils."[6]

Holton of Vermont introduced in the House of Delegates the resolution of Ludwig Weiss, which had been adopted by the Section on Cutaneous Medicine and Surgery. It states that "since there lies in the province of the medical profession the task of recommending to the respective State legislatures and municipalities means, not regulamentative, but social, economic, educative, and sanitary in their character to diminish the danger from venereal diseases, it is resolved that the Section on Cutaneous Medicine and Surgery invite the Section on Hygiene to cooperate with this section to bring about a propaganda in the different States looking towards the recognition of the dangers from venereal diseases and to arrange for a National meeting similar to the International Conference at Brussels." Sanders of Alabama suggested a committee of six members from the two sections "to stimulate the study in, and the uniform knowledge of the subject of the prophylaxis of venereal diseases and to present a plan for a national meeting."[7]

This committee reported at the New Orleans meeting in 1903 that there is an utter lack of laws to combat venereal diseases. "Seventeen States have the usual laws and sundry police regulations of general character against houses of ill fame, including specified nuisances therein, against soliciting in streets, and against enticing females under sixteen years of age." There was in no State a sanitary marriage law providing for medical examination of the contracting parties, no law against willfully or knowingly communicating venereal disease, and no municipal regulations in existence in any city in reference to venereal disease. There were police regulations of a general character, which were confessedly a dead letter; Detroit and Cincinnati had regulation on the continental plan. There was a scarcity of beds in every city for the accommodation of venereal patients. The committee again favored a National Conference on Venereal Prophylaxis, and suggested that the American Medical Association ask the accredited delegates from each State, or appoint a special committee to organize a movement in the different States to influence all State legislatures to appreciate the necessity of legislation against the venereal diseases. The committee recommended the appointment of a central committee organization to be in touch with the various State committees. The House of Delegates adopted these recommendations. It advocated the continuance of the committee to act as a central committee as suggested, the creation of cooperative committees to be composed of one member from each State appointed by the president of the State society, and it provided for a meeting at the St. Louis Fair in 1904 and advised trying to get $5,000 from Congress for that purpose. Evidently the committee failed in its effort, for I find no reference in medical literature to the proposed conference at St. Louis.[8]

At the 1904 meeting of the American Medical Association the Section on Hygiene presented a symposium on venereal diseases. In the House of Delegates the committee on venereal prophylaxis made its second report, which was most comprehensive. Attention was directed to legislative measures which minimize the ravages of tuberculosis by making it reportable to Boards of Health, and to prohibition and high license which "tend to curb the alcoholic demon." It was said that "government, State and municipal officials, university regents, and the educated public generally, are imbued with endeavor and good will to check the alarming spread of venereal disease." The general public, however, "dolefully ignorant, indolent, and unwittingly but criminally careless, must be reached, educated, and enlightened as to the importance, dangers of acquiring, and the dire consequences of disseminating venereal diseases." The committee reached the conclusion that "systematized action emanating from the medical profession—a dissemination of knowledge to teach the populace the hygiene of sexual life—is the first step to diminish the dire consequences of venereal disease." The recommendation was again made that National and State societies for combating venereal diseases be created, but the House of Delegates decided that the Section on Hygiene "do the work necessary for the opening of this important matter."[9]

At the Portland meeting in 1905 nothing was done relative to venereal prophylaxis either in the Section on Hygiene or the House of Delegates, but at the Boston meeting in 1906 the Section on Hygiene presented a special symposium on the subject; the crimes against woman and the relation of alcohol were also considered. The cordial cooperation of many who are eminent in the profession and in philanthropy made it possible to present a series of papers of very great practical value, which are now published in book form. In the House of Delegates certain resolutions relative to the advisability of continence, the necessity of teaching the public regarding venereal infection, and the desirability of reporting venereal diseases, adopted unanimously by the Section on Hygiene, were referred to the Committee on the Improvement of the Treatment of Uterine Cancer, but this committee took no action. It did, however, report in favor of devising some ethical way of instructing the people regarding matters of public health. It submitted a plan for the organization of a General Board of Public Instruction to be composed of members of the different sections of the American Medical Association.[10] At this year's meeting in Atlantic City it is hoped the committee's recommendation will be adopted, and in that event it is reasonable to suppose that the need of publicity in regard to the venereal diseases will receive appropriate attention. It is perhaps not too much to expect that the American Medical Association, now that organization is perfected, will take some positive action in venereal prophylaxis along practicable lines.

The International Conference, first held at Brussels in 1899, has been referred to. As early as 1902 it was hoped a similar conference might be held in America, but, as already stated, the hope was not realized. At the second Brussels conference, held in 1902, it was recommended that there be organized in all countries special societies "for the study of the best means of every order—moral, legislative, social as well as medical—to be employed in the prophylaxis of these diseases."[11] Such societies have been organized in Germany, France, Italy, Spain, Hol-

land, and other European countries. In February, 1902, the American Society of Sanitary and Moral Prophylaxis was organized in New York, and to-day also Philadelphia, Detroit Milwaukee, and Chicago have branch or similar societies. These societies vary in their activity, but whenever public meetings have been held, clergymen, teachers, lawyers, and public-spirited men and women from all walks of life have favored an educational campaign against the venereal plague, and have demanded an active propaganda which shall teach the truth.

Thus it is seen that at last there is a prospect of definite action along educational lines, and the outlook for consistent prophylaxis is encouraging. In the meantime there is work for every one of us to do. No educational effort regarding venereal diseases is adequate without full consideration of the hygiene of sex. Thus the attempt to limit venereal infection will restrict at the same time abortion, illegitimacy, infanticide, and other results of a misdirected sexual instinct. For several years past I have not hesitated to express my views on this important subject. I am now asked regarding actual means which are practicable, and I attempt to outline a plan of campaign, which, with certain modifications to meet local conditions, is to my mind feasible and desirable. Its first essential is frankness, telling the truth to everybody. Its details have to do with aiding parents to teach their children, helping educators, from the kindergarten instructor to the university professor, to impart consistent knowledge to their charges, showing the employer how venereal diseases incapacitate his employees, informing the public of the extent and seriousness of these diseases, the possibility of innocent infection, and the need of scientific treatment. This means the creation of a rational public sentiment which will appreciate actual danger and override and put down all maudlin sentimentality and all ignorance that parades as innocence, in the earnest effort to afford protection by an exposition of the truth.[12] Incidental to such an educational propaganda must be a revision of our school text-books on physiology, supplementary instruction by medical teachers, and the repeal or modification of our obscenity laws which to-day place every author of a popular book on sex topics at the mercy of an ignorant jury. As a further important incident in venereal prophylaxis the care of the prostitute, who is the chief source of infection, must be mentioned.[13] To accomplish any positive result the medical men of our country must be up and doing. The time has come when in every community their efforts will be sustained and encouraged. Their advice will be welcomed, their endeavor will be appreciated, there will be intelligent cooperation by the public, and the results obtained will be productive of good to all.

Furthermore, and this presents formidable obstacles to be surmounted, the public press must come to our aid in the dissemination of actual knowledge. Papers presented to medical societies and printed in medical journals are of relatively little value to-day when the profession acknowledges the need of teaching the public. To reach the people, the daily newspaper must print the truth so that the people may read it. My own efforts have failed to induce some of the leading periodicals of the country to publish any reference to sex topics or venereal disease. When, however, I addressed public meetings in Detroit, Meadville, and Erie, Pa., the newspapers favored [illegible] good reports, covering often one or two columns.

To [illegible] the usual attitude of the press, I instance one occurrence. When the National Purity Federation adjourned at the conclusion of its session in Chicago last fall, several clergymen and their wives, together with others interested in rescue work, visited the slums. My individual opinion regarding the value of such an excursion is immaterial, but in fairness it must be admitted that there was no more impropriety in it than there is when delegates to a medical convention visit clinics and hospitals. The reporters seized upon this incident and described all details, but a few words sufficed to report the praiseworthy proceedings of the meeting. Of the wealth of information furnished by rescue workers, clergymen, a few physicians, and noble-minded men and women whose lives are consecrated to the cause of humanity, only meager details, exploited in a sensational manner, reached the public; but the remarks of the saloonkeepers were reported *verbatim* and the actions of drunken denizens of the dives were described in full. The paper I had read by invitation was offered to the daily press and promptly returned with the explanation: "The policy of our paper has been to avoid discussion of the sex relation in our columns, and, therefore, I should not feel justified in publishing the article." Three other papers which I wrote for the public in language which several representative women in Chicago assure me is unobjectionable, were also refused publication by the *Arena*, the *Saturday Evening Post*, the Hearst syndicate, and the *Ladies' Home Journal*.

Prophylaxis in children is favored by removal of all sources of irritation which predispose to congestion of the genitals. Retained smegma under the prepuce, impacted secretion around clitoris, or adhesions of the parts, are easily relieved by simple surgical procedures, and cleanliness should be taught and maintained. The child should also be taught by reference to the flower, and the chick the reproduction of life from the egg. In simple language, it may be shown by reference to the dog, the cat, or other domestic animal, how the human animal likewise carries the egg within its body and gives birth to its young. Attention may be called to growth or development whereby the calf, for instance, becomes a cow, and in this connection salutary instruction in hygiene may be given, because it is easily realized that growth must not be impeded.[14]

As the boy approaches puberty he should be told of the sexual instinct which exists to insure the perpetuation of the species. It is a masterful instinct, because most important, but it should not be indulged until development is complete and the boy has become a man and has been privileged, under the restrictions of religion and civilization, to take his place as the potential head of a family. The new sensations that he experienced at puberty are thus understood and the evil of masturbation is known, because it has been explained as a practice prejudicial to health and development. The importance of the laws of health has been instilled into the child from the earliest moment when he was able to understand anything, and at this time the necessity of care is emphasized in relation to the newly awakened instinct.[15]

The girl should also know the truth. She should be told all that the boy has been told, and in addition that menstruation is the preparation of her body for the performance, when she is older and is married, of the sacred and important act of reproduction. She should understand that hemorrhage from the genitals is to be expected, and that, unlike hemorrhage from any other portion of her body, the loss of blood here is not dangerous, but salutary. She should be instructed in the care of her body during menstruation. She should realize that she is becoming a woman and that it is right for her to care for herself during the menstrual epoch, not only because

it insures good health, but also because by so doing she prepares herself for the fulfillment, in adult life, of the supreme duty incident to motherhood and the perpetuation of the species.

This much should be told every child by its parents, but alas! the parents themselves are too often ignorant or careless, and thus are neglectful of their duty to their children. Moreover, many parents fail to realize the need of this instruction, or at best they do not know just how to talk to children. They are apt to think it is a nasty topic and to exaggerate the value of a Christian home and surroundings of culture and refinement as the only necessary safeguards. Parents should be given to understand—and here the physician's duty becomes apparent—that the sexual instinct exists in every normal child, dormant to an extent, but easily awakened into pernicious activity by some chance occurrence, and often with the most deplorable result. Moreover, this idea of nastiness must be abandoned when reference is had to the most important of all functions. Parents must be taught regarding this imperious force in every human being, and must realize the necessity of imparting adequate and accurate information before unfortunate practices occur as the result of the irrational and fantastic explanations which will be volunteered by the child's immature playmates. I insist that the question is not as to the relative value of knowledge or ignorance, often falsely called innocence, but as to the imperative necessity for knowledge; the new sensations experienced by the child demand interpretation, and our duty should make us vigilant, so that a timely exposition of the truth may enable the child to repudiate impure suggestions, and thus escape disease and disaster. If this is done early there is little danger that the child will follow the immediate impulse, as has been said, "with an increase in the already dreadful evil of self-abuse."[16] On the contrary, the child will avoid all danger, because it is known and the possibility and advisability of continence is understood and appreciated.

But the child must know more, and in the imparting of further knowledge the parent and teacher are usually incompetent, and require the aid of the physician, who alone can speak with authority. He should talk in a friendly way to the child about conception and reproduction; he will tell of the venereal diseases and how they may be acquired innocently; he will explain about the dominant influence of the sexual instinct and will show how want of control is largely responsible for the existence of the unfortunate prostitute who is the chief purveyor of these loathsome and dangerous diseases. He will extol the dignity of virility; he will show the preeminent value of purity; he will inculcate a chivalrous sentiment of honor.[17]

The result is that each boy and girl knows that the physician is the best friend. The child realizes that the eminent practitioner has not forgotten that he himself was once young and exposed to similar temptation. He will feel that the family doctor can sympathize with him and can give sensible advice. He will hasten to consult him if nocturnal emissions cause alarm, if he fears he is hopelessly addicted to masturbation, or if gonorrheal symptoms appear. He will avoid the advertising quack, for he knows where to find a sympathetic friend willing and able to help him in any emergency.

Instruction must also be given to the young who live apart from the family. The employees of store and factory, the workers everywhere, the student, the farmer, the married, and the single, the rich and the poor—everyone must know the truth and understand the great danger.[18] Such a plan of education requires laborers in the vineyard, and each medical man should constitute himself a committee of one in his immediate neighborhood to devise the best means of imparting accurate knowledge. In some instances books like those of Dr. Lyman Beecher Sperry may be advised; in every school a medical lecturer should teach hygiene and the physiology of the whole body; at woman's clubs, secret society meetings, and in fact wherever there is a gathering of men or women, the opportunity should be afforded the medical man to speak on these important topics. Each county medical society should have a permanent committee to arrange frequent public meetings. It has been demonstrated in all parts of the country that such meetings are largely attended and that the people are eager to know the truth. In our colleges, especially our medical colleges, there should be regular public lectures on these topics so that all may learn. In addition, special pamphlets free from technicalities should be distributed freely, but in this endeavor to diffuse consistent knowledge, there is a serious obstacle to be confronted in the existence of certain United States laws in reference to the use of the mails. Obscene literature is declared unmailable and the author may be fined or imprisoned.

At first thought such a law seems just and desirable. We have all seen certain smutty books which excite our disgust. We shudder to think they may fall into the hands of children, and we are glad when such publications are confiscated and destroyed. Few of us know the law or appreciate its workings. None of us can give a legal definition of the word "obscene," because there is none. All statutes describe what is prohibited as lewd, indecent, obscene, lascivious, disgusting, or shocking. In the first English decision on record, Hicklin had sold a pamphlet entitled "The Confessional Unmasked." It was a political circular to promote the election to Parliament of men who would "expose and defeat the deep laid machinations of the Jesuits and resist grants of money for Romish purposes." It consisted of extracts from Catholic theologians, and was intended, as the author believed, to improve morality. Nevertheless, the court held the pamphlet to be obscene, and gave this test, which holds to the present day: "Whether the tendency of the matter charged as obscenity is to deprave and corrupt those whose minds are open to such immoral influences, and into whose hands a publication of this sort may fall." In another judicial decision there occurs this statement: "The matter must be regarded as obscene if it would have a tendency to suggest impure and libidinous thoughts in the minds of those open to the influence of such thoughts." Still another judge, after quoting these alleged definitions, remarked: "These are as precise definitions as I can give. The case is one that addresses itself largely to your good judgment, common sense," etc.[19]

Now, if I say triangle there is presented to the mind an object which may vary in many particulars, but which conforms to certain mathematical requirements in a manner that is a matter of common knowledge quite beyond dispute. If I say murder, arson, or burglary, we think at once of a specific crime, varying perhaps in degree and punishable in different ways in accordance with custom, but nevertheless clearly outlined and well defined. If I say obscene, who can say what it means? To every juryman it has a different meaning in accordance with his personality. The contemplation of nude figures in an art museum suggests no impure or libidinous thought to the artist or the man of culture; an inspection of the female genitals does not affect the gynecologist. The peasant woman is

shocked by the indecency of the society woman's bare neck and shoulders, and the society woman is shocked at the peasant woman's bare feet and ankles, especially if exposed in the city woman's parlor.

The most unfortunate circumstance in connection with obscenity law is that no man may know in advance if he be a transgressor. No man can foretell what will be another man's opinion about the probable tendency of a book upon those susceptible to its influence who may chance to read it. The practical workings of the law have been most curious and unjust. Haverlock Ellis's "Studies in the Psychology of Sex" were, I believe, wholly suppressed in England, and the German translation is denied admission into the United States. Another suppressed book is described by a former Attorney-General of the Post Office Department. He says "it consisted mainly of a description of the causes and effects of venereal diseases, and secondly of two circulars, one of which described in separate paragraphs the symptoms of various venereal diseases." This was held to be criminal. In 1892 a public school teacher wrote a book called "Almost Fourteen." He submitted it to his wife, the pastors of the Broadway Tabernacle and the Church of the Heavenly Rest, and to Dr. Lyman Abbott, all of whom indorsed it. The Rev. L. A. Pope, pastor of the Baptist church at Newburyport, Mass., placed the book in the Sunday-school library of his church. Five years afterwards an enthusiastic newspaper reformer of Newburyport, who had incurred the ill-will of many influential citizens by exposing the impurity of the city administration, the owners of houses of prostitution, etc., secured permission to republish the book in his paper. He was arrested, convicted, and fined.

In 1872, George Francis Train was arrested for circulating obscenity, which proved to be quotations from the Bible, and again, in 1895, John B. Wise of Clay Centre, Kansas, was arrested for sending obscene matter through the mails, which consisted wholly of a quotation from the Bible. In the United States Court, after a contest, he was found guilty and fined. It is to be remembered that courts have often decided that a book, if obscene in any part, is an obscene book within the meaning of the law. Of course, the Old Testament, like all books valuable for moral instruction, contains many unpleasant recitals. At the same time, its hygienic teachings are of more than historic interest, and in many instances apply with wonderful force to our present civilization. The fanaticism which induced Queen Mary to inhibit reading or teaching the Bible in churches, and which, under Edward VI., caused the burning of thousands of Bibles because of the immoral tendency toward private judgment involved in the reading of them, is still conspicuous in certain quarters, and would still dominate as in the past. Indeed, the desire to persecute, even for mere opinion's sake, seems to be an inherent characteristic of nearly every man of firm conviction and earnest purpose. Education alone can make us overcome this tendency and teach us the value of toleration which permits advancement by encouraging and liberalizing the study of what each man believes to be the truth.[20]

My friend, William Lee Howard, speaks of a young woman who happened to see a portion of a man's garter, which held up his silk hose. Upon her return home there began distinct, clear, and culminative erotic dreams. These commenced by the subconscious visualization of the garter, and the vital vision led up to what might be seen in a healthy, virile man. One day in a shop she saw a duplicate of her fetish, which she instantly appropriated. From fondling the article to manustupration and fetishistic masturbation was a short road. When the kleptomaniac was arrested for stealing garters a large collection of these articles was found in her bedroom.[21] I mention this case to show that under the usual definition the exposure of garters in a shop is obscene. Here was the "mind open to immoral influences" and "the tendency was to deprave and corrupt." Or, in accordance with another definition, we can truthfully say that the sight of garters had "a tendency to suggest impure and libidinous thoughts," because in this case "the mind was open to the influences of such thoughts."

Many other cases could be cited to show the incongruity and absurdity of the law. An author sent to jail in California finds his book recommended by innumerable clergymen, including several bishops, goes through the mails unchallenged for twelve years, and is suddenly declared criminally obscene and suppressed by a postal official. A book is found "not immoral or indecent at all" in Boston and suppressed by fines aggregating over $5,000 in Chicago. Another book goes through the Chicago post-office by the thousand each year and is excluded by the Boston post-office. Even judges have reached different conclusions concerning the obscenity of the same book, and several men have been pardoned because the President did not believe a book to be obscene which a judge and jury had declared to be so. Postal authorities have declared a book not to be obscene, and some State official declares it is obscene and arrests the vendor; sometimes conditions are reversed. In 1899 my own paper on the sexual act was refused publication on the grounds of obscenity by the editor of the *Journal of the American Medical Association* and by two of the trustees, and commended by another trustee.[22] It was copyrighted after submission to the postal officials at Washington, and for seven years went through the mails to physicians in all parts of the civilized world without a word of protest. I make this statement now because the edition is exhausted and the pamphlet is no longer on sale. Otherwise, I confess I should be at the mercy of every ignorant, spiteful, or impressionable individual.

It is evident this state of affairs is intolerable and a serious interference with the work of diffusing accurate knowledge which is recognized as an important element in venereal prophylaxis. To be sure, certain judges have recognized that an impartial enforcement of the letter of the law would entirely extirpate the scientific literature of sex. They have, therefore, quite in excess of their power, made a judicial amendment of the statute excepting from its operation books circulated only among physicians. Such judicial legislature is made under the pretense of "statutory interpretation," and involves the ridiculous proposition that a book which is criminally obscene if handed to a layman, changes its character if handed to a physician; it assumes that a scientific knowledge of sex is dangerous to the morals of all those who do not use the knowledge as a means of making money in the practice of medicine. Thus, medical books which treat of sex circulate among members of the profession as a matter of tolerance, in spite of the law, and not as a matter of right under the law.

If a remedy is asked for, I must confess my inability to give a complete and practicable recommendation. My friend, Theodore Schroeder, the eminent attorney for the Free Speech League of New York, argues that all obscenity laws should be repealed. He claims that obscenity is not an objective fact, not a sense-perceived quality of literature or art, but is only a quality or contribution of the view-

ing mind, which, being associated with some ideas suggested by a book or picture, is therefore read into it. He shows how custom sanctions certain expressions which otherwise would shock us. For instance, we may speak of the mare to those who would take flight if we call the male horse by name. With like unreason, we may speak of an ox or a capon to everybody, of a gelding to many, but of a eunuch to very few without giving offense. He claims the right for every adult man or woman to study sex if they want to do so as freely as they may study law, theology, architecture, or any science. The Agricultural Department of the United States distributes information on the best methods of breeding domestic animals, but the advocates of a higher stirpiculture for the sake of a better humanity are often sent to jail.

I am indebted to Mr. Schroeder's writings for the facts regarding obscenity laws which I have submitted to you. I have told him his argument was unanswerable. At the same time I cannot bring myself to believe it is practicable to let down the bars completely. The marriage guide, which exaggerates symptoms and serves as an advertisement for the mercenary quack and the lascivious pamphlets and photographs which are imported from France, cannot, in my judgment, be properly exposed for sale. If there is here an infringement of personal liberty, I beg to remark that all law is a compromise and that the good of the majority must ever be the chief object of our concern. While I make this admission I also insist that the proper education of the public is of supreme importance, and that all restrictions to a diffusion of knowledge are inimical to the public good. Of course, this statement does not apply to children. As an adult, it is my right to read bawdy books if I want to do so; as a minor, it is a matter of discretion in others what I shall be permitted to read. No adult has the right to limit the opportunity of another adult to know anything that is to be known, but a parent has the right so to limit the child's opportunity. If parents had access to all scientific books upon sex, and our schools did their duty in the matter of instruction, the second generation would find all morbid curiosity dispelled, and the quack, who thrives only on ignorance and fear, would be put out of business by the general intelligence that would prevail. For the present perhaps it were well to demand that all writings which are indorsed by State Boards of Health, reputable medical societies, the National Educational Association, or other organizations which are acknowledged to have the welfare of humanity at heart, should go through the mails and be offered for sale without placing the author in danger of fine or imprisonment. This much we can consistently avocate today, and, with our State and county medical societies properly organized, we can at once hope to secure relief from the oppressive, uncertain, and inconsistent law that now restricts unjustly our efforts in venereal prophylaxis.

The prostitute question must also be considered in a common sense manner, free from sensational sentimentality. The prostitute is a creature of our civilization; as a factor in the dissemination of venereal disease, she becomes of interesting importance in every rational attempt at prophylaxis.[23] At the recent meeting of the State Medical Association of Texas, I detailed my views regarding prostitution. For that reason I need now but briefly refer to the fundamental principles which underlie every judicious consideration of the subject. I do not speak now of the Christian charity which should protect the young and save the innocent, of the injustice which condemns the one false step on the part of the girl and condones continued and excessive libertinism on the part of the young man. I speak here only of the prostitute as an agent for the propagation of venereal disease, and I remark first that it is within the limits of the truth to say that it is only a question of time before almost every prostitute becomes diseased. For this reason, if for no other, she should become and remain the object of special concern. It is most unfair to condemn measures that do not eliminate all disease at once. Because we cannot examine all prostitutes several times a day, it is unjust to say we should do nothing. Because the men cannot be subjected to inspection and quarantine, it is absurd to say no one should be isolated. If I find a prostitute diseased this morning and put her in the hospital, I know that she will infect no man to-night. Thus, in any event, one source of contagion is eliminated, and at least some good is accomplished.[24]

It seems impossible even for medical men to consider prostitution calmly and scientifically. At once there is raised a cry against "recognition" or "legalizing." Someone says there must be no compromise with sin and no dickering with vice. Then someone else quotes from the Bible and says "her feet take hold on hell." That statement usually settles the matter and no one has a word to say in reply. Now, I claim in this connection that we should minimize prostitution by an educational effort such as I have tried to outline, and by economic measures, which, among other things, increase the young girl's earning capacity and diminish her expenses. With the prostitute we should limit the spread of venereal disease by instruction in prophylaxis and by increasing our inadequate facilities for treatment.[25] These matters I have considered so often that I will not now impose on your courtesy further.[26] Since, however, the time for action has arrived, it is but proper that the State Medical Society of Illinois should be put on record as advocating well-recognized methods of prophylaxis now adopted by other medical organizations. For that reason I offer the following resolutions:

Whereas, We appreciate the rational crusade against the venereal plague which has been inaugurated in the United States, and wish to cooperate in every way in our power in all efforts to limit disease, to diffuse scientific knowledge, and to increase general healthfulness and happiness; be it

Resolved, That we favor in the Illinois State Medical Society the appointment of a standing committee on venereal prophylaxis which shall direct an active and vigorous campaign against the spread of venereal diseases, and shall report annually to this society regarding legislative, educational, restrictive, preventive, and therapeutic means best calculated to limit these diseases.

Resolved, That we recommend the appointment of a similar committee by every county medical society which, in harmony with the committee of the State society, shall act for the best interests of the community, in reference to prophylaxis, as mature deliberation shall determine to be most desirable.

Resolved, That while deprecating the sensational and alarming statements promulgated by the mercenary charlatan, we favor an educational propaganda which shall teach the truth, and that we advise in every community increased facilities for gratuitous treatment of all venereal patients.

Resolved, That in lieu of all present laws against "obscene" literature, we favor that the young be safeguarded against corrupting information by laws which shall put the postal matter of the immature wholly within the control of parents or guardians. We favor such other proper legislation, having ap-

plication only to the immature, which shall be so definite in meaning that there will be no doubt as to what is prohibited, and which will not preclude any adult from acquiring full and complete information regarding all scientific subjects.

Resolved, That we recommend the amendment of all National and State laws so as to declare that no prohibition in them contained shall be deemed to apply to any serious discussion of sexual facts or conditions or of any branch of science dealing with sexuality, or of any sociologic, moral, or religious questions connected therewith, as against those who write or publish the same for circulation or exhibition in good faith among persons of legal age, and who, in good faith, deliver them by mail, express, or otherwise, only to individuals of legal age.*

ADDENDUM.

At the recent Atlantic City meeting of the American Medical Association there were presented in the Section on Hygiene and Sanitary Science papers which considered syphilis and gonorrhea as factors of depopulation and gonococcus infection as a cause of blindness, vulvovaginitis, and arthritis. These three papers represented all reference made to venereal prophylaxis at this meeting. The masterly oration on State Medicine did not mention the subject. A Board of Public Instruction on Medical Subjects was created to arrange for the publication of suitable articles through the public press, keeping on file in a central bureau suitable articles in pamphlet form for general distribution to the public, the organization when possible, of public courses of lectures in cities which have medical schools and in other localities under the supervision of county medical societies and the dissemination by circular letters of matters of general moment to the medical profession.[27] This board is nominated by the president and is not composed of a definite number from certain sections as was originally suggested by the committee. No report was made on the resolutions, introduced a year ago at the Boston meeting, regarding the healthfulness of continence, the advisability of reporting venereal diseases and the duty of State boards of health to educate the public regarding venereal infection so, by direction of the Section on Hygiene and Sanitary Science I called up the matter in the House of Delegates and, on motion of Dr. Craig of Pennsylvania the resolutions were taken from the committee that had failed to consider them and referred to the Committee on Hygiene and Public Health. This committee asked for a more detailed statement as to what is meant regarding "control of Boards of Health" in reference to venereal diseases, it favored an educational propaganda through proper channels, which recommendation, on motion of Dr. Frank Billings of Chicago, was approved, and it also favored the resolution of Dr. Morrow regarding the healthfulness of continence, but, strange to say, the House of Delegates laid on the table the report of the committee on this resolution as well as the resolution itself. No action was taken on my own resolution, introduced the first day of the meeting, which commended to all educators the advisability of teaching the truth regarding the healthfulness of continence, the physiology of the whole body, and the possibility of innocent infection, and which favored a modification of existing obscenity laws so that the young might be safeguarded against corrupting information, while pamphlets emanating from societies of recognized standing might go safely through the mails and be offered for sale without danger of arrest to the vendor.

*The resolutions were adopted unanimously by the Joint Session of the Medical and Surgical Sections.

SEPTAL PERFORATIONS: THEIR CLOSURE BY PLASTIC OPERATION.*

By CHEVALIER JACKSON, M.D.,
PITTSBURG, PA.

The enlarging of a septal perforation to stop the "whistling" of a small perforation is, in the writer's opinion, an obsolete and unjustifiable procedure. Small perforations are very easily closed by a simple operation, and great relief will be afforded from the manifold annoyances which accompany such perforations.

The operation is, briefly, as follows: The inferior turbinal of one side and the septum are anesthetized with cocaine and adrenalin in the usual way. Then a long, tongue-shaped flap is made in the inferior turbinal by two parallel incisions, using Kyle's right-angled tonsil knife or Ballenger's or Freer's, or Watson's septal knives. This flap is made of the entire thickness of the mucosa with some of the submucosal tissues. It is free posteriorly and attached anteriorly. It must be at least 6 millimeters larger vertically than the perforation, and must be of very ample length, usually almost as long as the turbinal itself (Fig. 1). After the flap is raised, the

*Read before the Pennsylvania State Medical Society, September 24, 1907.

edges of the perforation are freshened with a cataract knife and the flap is brought forward in the position shown in Fig. 2, and is stitched in place with silk sutures, using Killian's or Yankauer's suturing instruments.

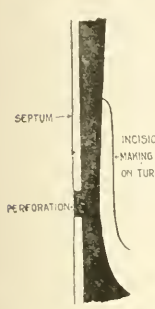

FIG 1

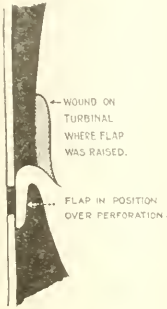

FIG 2

In case of a very small perforation, the operation is now completed. In case of a larger perforation it is better to duplicate the operation on the other side. Usually no packing is required, but if it is deemed necessary it must be placed behind the flap before the flap is sutured. Then the packing may be completed after the flap is sutured.

The result of the operation, when the flap unites with the septum, is to create a synechia. But this is very simply removed by clipping out a section of the bridge formed by the flap and inserting a strip of bismuth lint, which is left for five days.

It is absolutely essential that all excess of the inferior turbinal be removed, as, if the turbinal is hypertrophic, a troublesome synechia will result. The turbinated bone must be resected after the flap is raised, so that the healed turbinal will be far out of contact with the septum. If this be watched, and the mucosa around the edge of the perforation be properly freshened, an excellent result will follow. Should the small opening remain after the first operation, a second operation will close it. It is preferable for this reason to operate only upon one side,

FIG. 3.

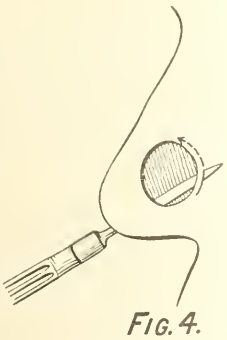

FIG. 4.

leaving the other turbinal untouched, so as to be fully available for closing what remains of the perforation after the healing of the primary operative wound. The best method of freshening the edge of the perforation I have found to be to transfix with a cataract knife the edge at the bottom from the operated side (Fig. 3) and carry the incision carefully forward, then upward along the anterior edge, as shown by the dotted line, never allowing the knife to cut out through the edge until the topmost limit has been reached. Then the knife is withdrawn from the nostril on the side whose turbinal is to be used and is inserted into the other nostril, transfixing the bottom margin with the knife whose cutting edge should now be backward. The knife is then passed backward and upward along the posterior edge (Fig. 4) until the top of the perforation is reached and the other denudation met. This encircles the perforation on the side of the turbinal that is to furnish the flap with a beveled denuded surface (Fig. 5), to which the flap will promptly unite.

One of the greatest merits of the operation is that it can be used on cicatricial septa and on those where the cartilage has been removed by a submucosal operation.

SYPHILIS AND MASSAGE.*

By ROBERT W. TAYLOR, M.D.,

NEW YORK,

CONSULTING GENITOURINARY SURGEON TO BELLEVUE AND CITY (CHARITY) HOSPITALS.

Among the curiosities of the literature of syphilis are those cases in which operators of various grades and kinds have been the medium by which this far-reaching infection was communicated, sometimes sporadically and again in epidemic form. Many articles on this subject relate to vaccinal syphilis, in which the victims were reported by the hundreds. To-day this mode of infection is practically unknown.

A singular mode of transmission of syphilis is said to occur in Roumania and Russia. It is the custom in these countries to attribute all affections of the eyes (and trachoma is very frequent) to foreign bodies, for the relief of which there is a class of women called leeching oculists who cleanse the eyelids with the tips of their tongues. One of these women having mucous patches in her mouth conveyed syphilis to many persons; in some instances to whole families. Large numbers of cases have been reported in which lues was transmitted in the operation of tattooing. According to one recital a tattooer who practised his calling for years over a large area of territory was arrested in Philadelphia, where, and in the vicinity, fifteen syphilitic infections were proved to have been caused by his ministrations, he having moistened with his saliva the tattooing instruments. In his mouth were discovered mucous patches, from which he had suffered for a year.

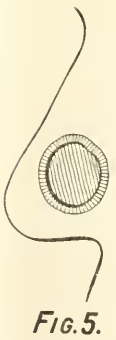

FIG. 5.

We no longer hear of luetic infection from the introduction of soiled catheters into the Eustachian tubes, a not uncommon accident many years ago.

A few old-time instances of syphilitic infection resulting from skin-grafting were reported in the past. They are hardly to be feared in these aseptic days.

Infection by means of dry and wet cups and by breast drawing is to-day, as of old, probable, but no recent record of such accidents has been published.

Though operations in dentistry have been cited as the starting point of syphilis in many cases, there

*Read before the Sixth International Dermatological Congress in New York, September 13, 1907.

is not as yet a thoroughly authenticated case of this mode of infection.

While in many instances the good offices of the barber seem to have been the precursor to luetic infection, there is not on record a perfectly satisfactory history of a case of this accidental infection.

The culpability of both dentists and barbers, as operators, should be established on clearly cut, salient, clinical evidence. Hazy, ill-reported cases should be rejected.

I desire to call attention to a mode of syphilitic infection by an operator which is as yet unmentioned. The ungarnished history of the case is as follows:

On February 8, 1907, a gentleman, 38 years old, undergoing treatment for chronic posterior urethritis, casually called my attention to a group of lichenoid lesions seated over the prominence of the right gastrocnemius muscle. He is of stout build, shows a tendency to obesity and complains of mild, fugitive rheumatoid pains of uncertain seat and duration. He is a spare drinker of alcoholics, but much given to the pleasures of the table. He is of hirsute development and has had mild intermittent attacks of scattered lichenoid eruptions seated around hair follicles. He had severe gonorrhea in 1897, and a relapse in June, 1903. From the latter date to this time he has had gleet, for which he sought treatment when he saw fit. He never had syphilis, as shown by his statements and several exhaustive examinations by me. The skin lesions, nine in number and sparsely scattered over an area of three inches, were conical in structure, of the size of two lines, distinctly elevated, lichenoid in character, and of a dull red hue. They were non-pruritic, whereas in the past itching had been a concomitant of his hair-follicle-hyperplasia. I attached little significance to the present crop and concluded that cold and heavy flannels were the exciting causes. A camphorated zinc ointment (Lassar's formula) was ordered for inunctions and as a plaster. No internal medicine was given.

On February 20 the patient complained that his leg lesions were worse. I found the papules much increased in size, rather more elevated and scaly, resembling flat papular syphilides. The central lesions were redder than the rest, decidedly excoriated, resembling typical chancrous erosions. There was brawny induration over the morbid area; no heat nor tenderness. My suspicions were aroused. Further examination showed thickened, goose-quill-like vessels and lymphatics curving behind the inner condyle of the femur, and moderate hyperplasia of the ganglia at the saphenous opening and in the groin. The accessible ganglia of the body were very perceptible. The local treatment was continued and a placebo was ordered. There was no systemic reaction and no spirochætæ pallidæ were found in the blood at any time.

Matters went on uneventfully until March 7, when a group of eight scattered papules was exhibited to me, seated over the prominence of the left deltoid muscle. These lesions were similar, but less developed than those over the right leg. All the lesions at this time had the characteristic raw ham-like appearance of syphilis. In a previous interview the patient had asked inquiringly whether these exanthems had probably been caused by massage, which he took twice a week; at this time he stoutly expressed the conviction that they were thus produced.

On March 18 a typical erythematous syphilide was seen over the whole body, the lesions being markedly papular in the neighborhood of the leg and shoulder initial lesions. The usual symptoms of active secondary syphilis were present: mild fever, rheumatoid pains in joints and muscles, early incipient alopecia, and pharyngeal hyperemia. The patient was at once placed on active treatment; hypodermic injections of the bicyanide of mercury, and blue ointment was rubbed into the initial lesions. The patient responded promptly and well to treatment, and to-day, September 30, has no general eruption. The initial lesions having faded, left coppery spots; the adenopathies are slowly subsiding.

Here, then, is a case of syphilitic infection seemingly caused by the manipulations of the masseur-operator. The patient had not had coitus for months nor had he dallied with any woman. His habits were correct and the only person who had access to his legs and arms was the masseur.

He convinced himself that he had suffered from blood poisoning.

My interest in the case prompted me to run down the operator and ascertain his physical condition. This search took much time and demanded tact, prudence, and patience. After several weeks' inquiry I luckily found a companion of the operator, a male nurse. Through him I learned beyond a doubt that my patient's masseur was affected with recent active syphilis, and that he had had severe sore mouth and a swollen neck. The information was forthcoming that the buccal and pharyngeal lesions, thought to be diphtheritic, caused the patient much discomfort and to copiously secrete saliva; that he constantly slobbered and dried his mouth with his fingers and the backs of his hands. This action he performed very frequently. The mystery of my patient's syphilis was thus fully cleared up.

Here, then, is the case of a healthy man having simple efflorescences over the legs and arms who was infected by a luetic masseur in his vigorous ministrations, his hands becoming soiled with the secretion of mucous patches. The teachings of the case are evident.

The course of syphilitic infection here presented is clear; its salient features are as follows:

1. The development of multiple syphilitic chancres, 17 in all.

2. The evolution of successive chancres in the intraprimary stage, a not uncommon instance of superinfection. The first lesions appeared presumably about 38 days before the secondary climax and their sucesscors 11 days before that event.[1]

3. The development of preponderating papular lesions just beyond and near the sites of the hard chancres,[2] whereas elsewhere the eruption was erythematous.

THE PRESENCE IN VACCINE VIRUS OF BACILLI AND SPORES RESEMBLING THOSE OF TETANUS.

By ROBERT N. WILLSON, M.D.
PHILADELPHIA

Five years ago I published an analysis of fifty-two cases of tetanus following vaccinia, which was prefaced by this paragraph: "The following analysis of a large number of instances of tetanus in the course of or following vaccinia was prompted by the occurrence of a case in the practice of the writer, and by its fatal termination in spite of an early diagnosis and heroic treatment. During the five months that have succeeded the report of this case

before the Philadelphia County Medical Society, an attempt has been made to ascertain the details of such a number of similar cases, both in recent and past years, as would warrant a conclusion as to the source of the tetanus infection" (*Journal A. M. A.*, May 3, 1902). The analysis, which was exceedingly thorough and careful, seemed to justify the conclusion that "a secondary infection, and one occurring as a rule about the time of the acme of the vaccinia, is indicated by the otherwise discordant chronic incubation period and acute symptoms, by the almost uniformly fatal termination, and by the severity of the course of the disease; also by the severity of normal vaccinations with the same virus, by the simultaneous deaths from tetanus known to be due to other causes, by the diminution in the number of such cases now that continued aseptic care is more generally exercised, by the fact that in every case in which particulars are known overabundant opportunity was offered for such secondary infection, and, finally and most important, by the absolute failure of all bacterial and inoculation experiments in the lower animals and man to indicate the presence of the tetanus microorganisms or their toxin in the virus." In short, I was forced to conclude upon the evidence that the tetanus infection was introduced, not with the vaccine virus, but subsequent to the scarification and at a time near the acme of the vaccinia.

The article was already in type, and the issue of the *Journal* probably printed, when I found it necessary, owing to a new and somewhat confusing series of culture experiments, to set myself right with the medical public that would read my still genuine conclusions in the course of a few days. I had, whether fortunately or unfortunately, procured samples of virus, as before, from three prominent manufacturing firms, of a date corresponding with that used prior to the then recent epidemic. I cultured in bouillon of one make the dry point, the glycerinated point, and the glycerinated tube virus; of the second, the dry point and the glycerinated tube; and of the third, the glycerinated tube alone.

1. From the first make of virus I obtained, after incubating at body temperature for twenty-four hours, the following: The dry point—Bouillon very turbid; no surface growth; no odor; mixed culture, including diplococci, streptococci, staphylococci, and many unknown forms. The glycerinated point—Bouillon orange yellow, turbid; ivory point could hardly be seen in the tube; no surface growth; a nasty, fetid odor, resembling closely that of a neglected vaccine wound; a mixed culture of bacilli and spores resembling tetanus, with the bacillus subtilis. The glycerinated tube virus—Very slight turbidity; no surface growth; no odor; diplococci and staphylococci.

2. From the second make of virus: The dry point—Considerable turbidity; no surface growth; no odor; diplococci and a bipolar bacillus resembling *Bacillus subtilis*. The glycerinated tube virus—Slight turbidity; no surface growth; no odor; pure culture of encapsulated diplococcus, morphologically resembling the pneumococcus, Gram positive.

3. From the third make of virus: The glycerinated tube—Slight turbidity; an extensive growth on surface of bouillon, dirty white, like parchment; no odor. (Report of microscopic examination has been lost.)

It will thus be noted that all cultures were negative, except that of the glycerinated point of make No. 1, from which a suspicious growth was obtained. Of this point not only the ivory, but the virus and also the sheath were cultured separately in about 15 c.c. of bouillon. By good fortune, there remained one point in the box from which had been taken that which had given the suspicious culture. In order to determine whether the infection was one of a single point, or of the virus, and from what portion of the point came the tetanus appearing organism, I cultured again, and this time separately, (*a*) the virus from the point, (*b*) the ivory point itself, still carrying some virus, and (*c*) the scabbard or sheath, also carrying virus.

From each of the three tubes I obtained the same orange-yellow color at the end 24 hours' incubation at body temperature, and under the microscope the same spores and bacilli as before, indicating, of course, their presence in the virus.

I then undertook, in the middle of a busy winter's clinical work, the following experiments:

Series I.—1. Inoculated a white mouse at the base of the tail with 0.3 to 0.4 c.c. of the turbid culture containing the suspicious bacilli. After six hours this mouse was rigid and dead. No convulsion. 2. A second mouse, inoculated also at the base of the tail with 0.5 c.c. of the same fluid, died in convulsions eight hours later.

Series II.—1. On the afternoon of the same day I inoculated a full-grown and active white mouse with 0.3 c.c. of the suspected culture, also at the base of the tail. Six hours later very stupid; respirations cannot be counted; hind legs stiff and drag after him. Two hours later marked contractures of legs and twitchings of lower limbs. Two days later recovered use of legs; very weak and nervous; then jerky movements of head and body; hind legs again useless. Died without convulsion, extruding urine and feces in death contraction. 2. Injected a young white mouse at the root of the tail with 0.1 c.c. of the same culture. One minute later died in convulsion, mainly of lower extremities. 3. Inoculated a full-grown white mouse at the root of the tail with 0.1 c.c. of the same culture. On the next day it was very stupid; paresis of lower extremities; marked twitchings; dragged posterior extremities. Three days later respirations very rapid; weak and paretic. Died during this night, urine and feces extruding during death agony.

As already stated, these crude and uncontrolled experiments were noted down and roughly described. The culture tubes (still containing the points, tubes, virus, etc.), as well as stained specimens, were shown before the Philadelphia County Medical Society on April 23, 1902. Visitors were excluded, in order that the confidence of the report might be assured, a step that seemed advisable, owing to the then excited state of the public mind over the epidemic of tetanus in vaccinia.

Unfortunately, owing to pressure of other work and possibly influenced by a reluctance to prove these organisms to be actually tetanus bacilli at such a time, the work was suspended, and my notes, as well as the stained specimens, have remained hidden away. No filtration tests to separate the toxin were attempted, and later on it proved impossible to obtain virus of even an approximate date. One year after the suspected culture, however, a glycerinated point was obtained from Dr. Simpson of Cleveland, the sole remaining point from a box, one of which had been used to vaccinate his own sister, who developed a month later a fatal case of tetanus. This point was cultured, but yielded only a few diplococci and staphylococci, and some unrecognized fungi.

I present, therefore, a series of fag ends—all interesting, but of no serious scientific value, apart from their evidence as to the association of bacilli

and spores resembling those of tetanus with the implements used in vaccination, and at a time corresponding closely with an outbreak of tetanus, synchronous with an epidemic of vaccinia.

What significance to attribute to the cultures—whether to consider them growths of tetanus or pseudotetanus bacilli—will remain a matter of conjecture until we see them otherwise than through a glass darkly. The method of culture which proved successful pointed to the pseudo form. The toxic results upon the white mice, and (as our brethren, the antivaccination fanatics, might suggest) the tetanus occurring during the course of vaccinia in human beings, seemed to favor the true tetanus germ. The morphology and the epidemic were all, in fact, they would have needed to prove their case. Dr. Flexner examined the stained specimens with me, and agreed that morphologically they were very suggestive. Yet the nature of the organisms was and is far from proven.

On notifying the manufacturing firm of my discovery, I was informed by them that a New York bacteriologist had "tested their virus and found a bacillus resembling the tetanus bacillus, but had not found it pathogenic." Also that "he had found that the tetanus bacillus would sometimes, when inoculated into animals, fail to produce symptoms."

Both of these characteristics were demonstrated to belong to the true tetanus germ by Huddleston in 1903, who not only found tetanus bacilli in the stools of the vaccine (formerly hay-fed, later milk-fed) calves, but also the fact that the bacilli could live in vaccine virus for some time; that they were more easily demonstrated by cultural experiments than by animal inoculation, and that "small amounts of the tetanus infection easily fail of demonstration, both by animal and by culture tests"—some animals living in spite of inoculation with tetanus bacilli, and some dying from other infections than that of tetanus.

The question immediately arises, were my original conclusions regarding the secondary and non-vaccinal origin of the tetanus correct or fallacious? And, if the latter, is there a constant danger, even if only slight, of primary infection by tetanus bacilli at the time of vaccination? The instances of tetanus during the course of vaccinia have not yet come to an end, occasional notices appearing in the various journals during the last five years. Many, moreover, must have been the unpublished instances since the period in which Jenner launched the vaccination habit. With hardly an exception, the recently published cases have displayed the same delay of two to four weeks before the onset of symptoms, and all tend to verify the theory of an outside, secondary infection.

I must hold to my former verdict, and not a whit less strenuously because of the discovery of tetanus or pseudotetanus bacilli in one out of nearly one hundred specimens examined. I have explicitly stated my belief, whenever I have discussed the subject, that the possibility always exists of tetanus bacilli finding lodgment in any lot of virus or on any individual point or tube. That it did so in the epidemic of 1901, however, and that the bacilli were trained to develop their toxin almost to the day or hour, remaining secreted until two weeks had flown by, and then crawling forth from nook and cranny to produce the usual acute symptoms, I decline to believe, nor have I yet heard an argument from those who seemingly do which would lead me to alter my attitude in this regard. When in half a hundred cases the incubation period is almost invariably from two to three weeks—to wit, that of the so-called chronic tetanus, recognized to be a comparatively mild and favorable type—and yet nearly all of the cases run a severe, almost fulminant, and usually fatal course, the natural assumption is that a later date of infection than the scarification is in evidence, and the case is one of acute infection, not abnormally and indescribably delayed. Add to this the fact that nearly every vaccine wound was treated with studied neglect, that on many filthy shields or filthier rags or clothing were used, that in at least four instances the victims either lived over or in stables, and that in two they had been throwing handsful of earth over one another a day or two before the appearance of the tetanus; consider the tetanus in the light of these admitted facts, and we must, I think, make haste slowly in crediting the vaccine virus with the tetanus epidemic. It requires a broad mind to reserve to one's self the privilege of considering that the great majority of cases were instances of secondary infection, due to dirt and neglect, while isolated instances may indeed have been due to such an unfortunate virus as that cultured in my experiment. We must take this high ground, remembering that no make of virus goes scot-free, since the record of each and all includes one or more instances of the so-called vaccine tetanus.

MANAGEMENT OF THE THIRD STAGE OF LABOR.

By JOHN W. WINSTON, M.D.,

NORFOLK, VA.

This stage is often looked upon as the least important of the three stages; but this is by no means true, for improper management of this stage has and will often lead to untold trouble. Few of us stop to think how disagreeable a leucorrheal discharge is, and how much suffering comes from displacement and congestion of the uterus. We all know the methods to be followed, but they are not always carefully followed, and the object of this paper is to add, if possible, to the comfort of the mother by making us more thoughtful.

The third stage, or placental stage, of labor may be described as beginning with the birth of the child and ending with the expulsion of the placenta, blood, and membranes, and the complete reaction of the uterus. After the child has passed all bleeding points below the internal os must be looked after, and all tears located. If the latter are in the cervix it is best to leave them to a later date, when the tissues in that part have regained some tone. If the tears are in the vagina, it is best to repair while the patient is still under the anesthetic, when they are small and when pressure from the passing placenta will not tear out the stitches. With the larger tears, it is best to place the sutures at once and wait for the passage of the placenta to tie. In all these cases care should be taken to avoid entering the rectum, and the vagina should be packed above to keep blood off the field. It is always best to place the sutures while the patient is under the anesthetic, for very often they cause a good deal of pain, even with the sharpest needles and the most skilful hands. A small tear furnishes a nidus for infection, and often the smallest laceration may form an ulcer and become very irritating if left unclosed.

It is not the object of this paper to describe the methods by which repairs are made, but the point in view is what to do in order that the involuting uterus may be retained in the best possible condition and position to involute with as little trouble on the part of nature as possible.

The position of the placenta is as well ascertained before birth as is possible, and at least we can know whether it lies on the contractile or dilatable portion. If the placenta is prævia, it and the membranes are taken at once, as they generally come away directly; but if retained and when not retained hot irrigation and packing is resulted to at once. Ergot in these cases is, of course, inadmissible, as it dilates instead of closing the sinuses. Much more could be said about the management in placenta prævia, but we are dealing with the placenta in the normal position (on the anterior and posterior walls touching on the fundus).

A vulval dressing of folded sterile gauze while waiting for the placenta is a good rule, for it indicates the amount of blood coming out and protects the gaping vagina from the dust that may be in the room.

Immediately after the child is born the uterus lies for a while in a relaxed condition, which is normal and need not be interfered with, unless it slowly begins to enlarge—that is, to fill up, when it should be made to contract, not by a digging process, which we often see the nurse practise, but by gentle rubbing over the whole ball-like mass. After the uterus has been induced to contract firmly, if bleeding then occurs, it is probably in the vagina or cervix, and should be located.

The hand must be on the uterus almost constantly from the time the child is born until the placenta is expelled from the vagina, and after this the uterus should be watched an hour, so that once empty it is not allowed to fill or partly fill again. Holding the hand constantly on the uterus does not by any means mean that it is needed all this time, but the object is to keep a steady contraction and to know when the placenta loosens. This loosening of the placental attachment is easily made out by the trained hand, and a bulging just above the symphysis tells us it is in the lower part of the uterine canal.

Until the placenta presents at the cervix gentle friction should be used over the external surface whenever contraction lets up, for often more bleeding than is necessary to accomplish separation will take place when the tension is relieved, and this unnecessary amount of blood lost is so much from the mother By clotting it may cause the sinuses to be held open and thus allowed to bleed. All mothers are supposed at this time to be prepared to lose blood, but in no case should we carelessly lose more than is necessary.

The placenta, according to Schultze's explanation, separates from the center in consequence of the contraction and crumpling of the uterive wall at the place of placental attachment and the resulting accumulation of blood behind its center. This cannot occur before birth because of the pressure of the waters. Duncan claims that the placenta separates at the margin.

Halzapel holds that the placenta presents at the internal os by Duncan's method and escapes by the Schultze mechanism. Williams says it is difficult to reconcile the contradictory statements, but it would seem justifiable to class both modes as normal, the Duncan method occurring most often when the placenta is in the lower uterus and the Schultze when in the upper. Usually the placenta enters the lower uterine canal within fifteen minutes after the birth of the child, but it may be much sooner, and often it is longer.

It is not right to wait in ignorance a certain time for the placenta, but we must be able to tell when it separates and where it is located after the separation.

When the placenta is in the lower uterus and entering the vagina, it is no longer acted upon by the uterine contractions, unless there is a quantity of blood transmitting the force. The abdominal muscles then do the expelling, and it is often the case that they are insufficient. The placenta, once loosened from its attachment, becomes a foreign body and its presence in the uterus can do no good, and as fast as the membranes will safely follow it should be taken away. Nature has made her best effort to get rid of it, and when she fails to finish the act there can be no objection to helping her. To remain in the uterine outlet means that it is acting as a dam to the blood behind, which becomes clotted; the clots harden and, by pressure on the uterine walls, hold open the sinuses, allowing the blood to flow.

Thorough contraction in the area of placental attachment is an important step against septic absorption, the entering of embol into the veins is prevented, bleeding is stopped, and after pains are almost done away with. In animals, expulsion is aided by traction on the cord, as the cord has to be torn off, and after separation the dragging cord pulls on the stubble it happens to catch. When there is nothing to hold the placenta, which is lying loose in the upper vagina, no objection can be raised to gentle traction on the cord until the membranes cease to be slack; but by this time, in most cases, the placenta has escaped the vaginal orifice and the normal amount of blood enclosed in the membranes has escaped from the uterus. Persistent contraction of the uterus should be maintained, or at least relaxation must not be allowed to remain.

At the moment of relaxation the uterus gives up its hold on the membranes, and then gentle traction will bring away without tearing or other damage. In most cases the loosening of the placenta can be ascertained from without, but in doubtful cases introduction in front of the placenta of a sterile gloved finger through a thoroughly cleansed vulval orifice can do no harm.

Expression is best started, best performed between the contractions, as the gate is then open and the hold on the membranes is let up. When the placenta escapes through the valva many advise twisting the membranes so as to make them stronger; these, if then carefully manipulated between contractile periods, generally come away in toto. If any should be torn off, those in sight are removed and the others left to nature.

If the loosened placenta has not been allowed to plug the opening too long, the gush of blood following the placenta empties the uterus, but when blood has been retained in the uterus too long clots often form. The uterus should be emptied of clots by external manipulation from the outside, which is effective in most every instance. Edgar advises giving a douche into the uterus in all cases, in order to have the uterine cavity entirely empty. Some not only advise against flushing the uterus, but even advocate leaving the expulsion of the placenta to nature. Ahlfeld states that when left to nature only 14 per cent. of the placenta will be expelled in two hours. The earlier the expulsion takes place properly the easier it is for the woman, the uterus is more natural in position, and the doctor spends less time.

When the placenta has not loosened in thirty minutes Credé's method should be tried, and if this fails the sterile gloved hand may be introduced and, by a pulling motion, remove it. When the placenta is very adherent, as in some of the syphilitic cases, it is best to let nature make the separation; but one should always remember that separation and expulsion are two entirely different things.

The longer a uterus has to wait to come to its

postpartum size the less contractile becomes its tissues. After quick expulsion of the placenta, the uterus is more liable to hemorrhage than if we wait for the sluggish abdominal muscles; but, on the other hand, it is more contractible, and closes the vessels better, and takes a better form.

Immediately after the placenta is expelled the uterus is looked to, and if firmly contracted is left alone, but if relaxed, it is kneaded over the whole surface until it contracts. The uterus is treated at frequent intervals in this manner for one hour, at the end of which time it is safe to leave alone, as it should be, and often we could leave it sooner. It is best, however, to adhere to this rule, for a uterus may act well at first and then become stubborn; or, again, it is slow at first, but later contracts firmly.

When hemorrhage is present, if it is from a torn vessel in the vagina or cervix, the vessel must be tied; when the bleeding is from the placental site, the cause (as clots) should be removed and the uterus stimulated to contract by the proper manipulation or heat. Hot water in the uterus should be at 115° F., as below this point it does not work well, and above will cause subsequent relaxation. Other remedies are inferior to this, even when they are on hand, and hot water can nearly always be had in readiness. Application of the child to the breast takes too much time, and does not serve the purpose in a serious case. Vinegar and other astringents have been recommended, but seldom need to be used.

When the hemorrhage is from the non-contractile portion of the uterus, as in placenta prævia, the treatment is to avoid contraction of the upper portion and pack until coagulation does the work.

Rupture usually belongs to an earlier stage, but when present the bleeding points must be caught up and the tear repaired.

Edgar advises the postpartum douche to wash away any loose material and help to protect against infection, but no infective material in ordinary cases should be introduced, and the washing is entirely unnecessary. When used, one should avoid too much intrauterine pressure, as it may dislodge some clot into the circulation. Williams has shown that the vagina is freer from infective material before than after a vaginal douche in a series of tested cases. Edgar claims that you have a cleaner uterus and more comfortable vagina after irrigation. After all these things have been done the parts are cleaned and dressed, and the woman is made comfortable in bed and allowed to rest.

Afterpains will not amount to much if the uterus has been properly manipulated, as clots will not be present to cause irritation. Afterpains are not only disagreeable, but they do material harm by balling up the upper uterus and thinning out the cervical portion, which a few hours after labor should begin to regain its tonicity.

Concerning the use of ergot, we may say that it is at least a convenient thing in the busy man's hands, but no one can dispute that it has serious disadvantages. Never use ergot when eclamptic signs are present. In its favor may be said that it is a safeguard against hemorrhage in high placenta at the third stage, and should be used when the nurse is not skilful. It closes, or rather keeps closed, the sinuses, and is a safeguard against the entrance of infective material into the circulation (blood and lymph). If it caused the whole uterus to contract equally no one could raise an objection to it, other than it causes a too steady contraction, which holds the membranes to the wall tightly; but it does not cause the whole to contract alike, as it thickens the portion above the retractive ring and thins out and lengthens the lower portion of the uterus, that portion on which the heavy upper part is supported.

The supported portion becomes heavier all the time that the neck (the supporting portion) is becoming elongated and thinner, and the point is reached in some cases when the support fails; then the uterus bends. A uterus thus verted into an abnormal position must so remain until nature replaces, and this will not happen if it is unduly congested. In many of the cases it is remarkable to see how well nature handles them. The displacement itself causes congestion and retards involution, and our object is to prevent in all cases the first displacement, for we do not know what the result is going to be.

Lastly, we come to the abdominal binder, the application of which I am sorry to say is familiar to all; it has been so generally used and that women know its imagined comforts so well that the young man fears not to apply it. Having tried it in my first hundred cases and having left it off in my last fifty, I am prepared to say that it does not add in any way to the comfort of the patient other than to ease her mind. Williams says that it is responsible for many displacements and versions, and one has only to remember the direction of the axis of the uterus and the strength of its neck at this time not only to believe, but to know, that this is true.

In my list of cases it was remarkable to notice at the end of two weeks the difference in the uteri of those wearing the binder and those without it. Without the binder the displacements were almost nil, and involution proceeded faster in spite of the fact that Edgar says that the moderately tight binder promotes involution of the uterus.

With the patient in a recumbent position, how the pressure of an abdominal binder can help to preserve the form is hard to see, but anyone can see how pressure pushes the uterus backward. Edgar claims that it prevents splanchnoptosis and sudden filling of the abdominal veins; but the patient should not be allowed to take a perpendicular position until it is time for the pelvic binder. The first cannot occur with the patient in a recumbent position, and the filling of the veins from release of pressure will occur before the abdominal bandage can be applied, if it is going to happen at all. Pressure on a muscle does not develop it, but often makes it flaccid and causes atrophy.

After the patient begins to walk around the pelvic elastic or muslin support helps to preserve the form, as it supports the abdominal muscles that then have some tendency to sway down. The muscles need support and massage when they are strained, but never pressure. The pelvic binder is a convenient way to hold the vulval dressing and causes no pressure on the uterus.

Corrosive Sublimate.—It is said that much less pain is caused by solutions of bichloride of mercury when applied to mucous or raw surfaces if they are made up with normal salt solution instead of water.

A Simple Nutrient Enema.—After abdominal section (and some other serious operations as well) rectal feeding becomes a necessity. An excellent nutrient enema is made by dissolving a tablespoonful of sugar in a teacupful of hot water and boiling in it, for a few minutes, a teaspoonful of starch; add a wineglassful of wine; beat up two eggs in a tablespoonful of milk, and mix with the other and inject. It may be repeated every four to six hours until the patient is able to take nourishment by the mouth.—*American Journal of Clinical Medicine.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR

PUBLISHERS

WM WOOD & CO., 51 FIFTH AVENUE

New York, October 12, 1907.

THE REPORT OF THE SURGEON-GENERAL OF THE ARMY.

In his report to the Secretary of War for the fiscal year ending June 30, 1907, Surgeon-General O'Reilly states that the health of the army during the year was very good, the admission rate having been 1,276.88, compared with 1,205.97 for the previous year, and 1,833.11 for the septennial period 1898 to 1904. The deaths from all causes numbered 358, equivalent to a rate of 6.11 per 1,000 of strength, compared with 6.28 for the previous year, and 14.62 for the period from 1898 to 1904. The death rate for disease was only 3.28, the lowest since the occupation of tropical countries, and comparing favorably with the rates prior to 1898. As a cause of death tuberculosis led, with a rate of 0.77 per 1,000, which was greater than that for the previous year. Typhoid fever came second, but in this there was an improvement over the rate for the two preceding years. Pneumonia showed a death rate of only 0.24 as compared with 0.32 for the previous year, but the greatest improvement was in diarrheal diseases, the rate of which was less than half as great as last year, being only 0.09, as compared with 0.20. The morbidity rate for malaria was higher than last year, and has been steadily increasing since 1904; the rates for admission and noneffectiveness were 107.67 and 2.30 respectively, compared with 88.85 and 1.85 in the previous year. It is astonishing to learn that screening against mosquitos as a protective measure is practically neglected in the Philippines. The latest reports received in the Surgeon-General's office show that in the department of the Visayas not a single hospital is screened, while the department of Luzon has but three buildings or parts of buildings thus protected. Recommendation has, however, been made that all barracks, quarters, and hospitals used by American troops be thoroughly screened with 18-mesh wire gauze so as to exclude all mosquitos. In view of the facts that typhoid fever and other infectious diseases are often transmitted by flies and that flies breed especially in horse manure, recommendation has also been made that all stables at military posts be provided with a fly-proof room or bin for storage of manure, and that the manure be so treated as to prevent the breeding of flies therein.

Some excellent work has been done by the Board for the Study of Tropical Diseases. The first original discovery made by the Board was that of a new blood parasite, which they designated *Filaria philippinensis*. This new filaria, while so far as known not pathogenic, is of interest as being of common occurrence among natives of the Philippine Islands. Its presence in the mosquito *Culex fatigans*, as well as its life history in that insect, has been demonstrated. The Board has also investigated the prevalence of *Entameba coli* among healthy American soldiers, and has found it among a very large percentage, and demonstrated its continued presence in the intestine for long periods without producing symptoms. The Board also concludes that *Entameba dysenteriæ* may be readily distinguished morphologically from *Entameba coli* and is uniformly pathogenic. After an exhaustive study of dengue, the Board is unable to find any organism in the blood of infected persons, but has been able to reproduce the disease in susceptible individuals by intravenous inoculation of filtered and unfiltered blood from dengue patients. It has been able to prove the transmission of the disease by a mosquito, *Culex fatigans*, and concludes that the disease is not contagious. Yaws has been found to be quite prevalent among the natives in certain districts, and the *Treponema pertenue* was found in abundance in the lesions; the disease was also reproduced in monkeys inoculated with material from the lesions of yaws in the human subject.

Additional testimony regarding the evil results of the abolition of the canteen privileges is furnished in this report. Venereal diseases were, as in previous years, the most important factor affecting the efficiency of the army during the year; they had the high admission and noneffective rates of 190.44 and 13.09 respectively, showing little improvement over the corresponding rates for last year. There can be no doubt that these figures would be materially reduced were the temptations to frequent the low dives outside the posts lessened by the opportunity to find innocent amusement over a glass of beer in the post exchange within the lines. The high admission rate for alcoholism of 30.22 per 1,000 men recorded in the previous report is increased to 32.27 in the present one. Commenting upon these figures, General O'Reilly says: "This office concurs in the opinion expressed by most medical officers of the army that the abolition of the sale of beer in post exchanges has had much to do with the increase of venereal diseases and alcoholism in the army by driving the soldiers to disreputable resorts outside of the post and beyond the control of the post authorities."

Legislation to increase the efficiency of the medical corps is urgently needed. A bill providing for this passed the Senate last winter, but failed to come to a vote in the house of Representatives, although its passage had been urged by the President of the United States in his special message to Congress, by Secretaries Root and Taft, by the Chief of Staff, by the General Staff, and by the Surgeon General's office. In the leading foreign armies the proportion of medical officers is fifty per cent. greater than in ours, and they have further a large reserve of trained surgeons to draw upon in case of emergency while we have practically none. Under the existing law the number of commissioned officers in the medical department is 323, and actually there are but 302, leaving 21 vacancies, three more than there were a year ago. The number of applicants for admission is steadily falling off, only 24 having appeared for examination in April of the present year. At this examination no applications

were received from the medical centers of the country although, as General O'Reilly says, the hospitals in any one of the larger cities could furnish a sufficient number of well-qualified young physicians to supply the needs of the service if proper inducements could be offered. The lack of a sufficient number of medical officers has become very apparent since troops were sent to Cuba and there are now not enough medical officers left in this country to supply the positions that cannot be filled except by commissioned medical officers (recruiting service, larger military posts, examining and retiring boards). This inadequate supply of medical officers not only works injury to the Army, but is also a cause of considerable expense to the Government which has to pay for transferring patients to general hospitals and to larger posts where experienced medical officers are stationed, because many of the contract surgeons employed at the smaller stations are not sufficiently experienced to undertake the treatment of serious and complicated cases. Not only is the number of applicants for admission to the medical corps falling off, but the number of students in the Army Medical School is also diminishing, having been smaller during the last session than in any year since 1900. The reasons for this decrease are obvious. "The army medical service has lost much of its attraction for the bright young graduates from our best medical schools, and unless a remedy is soon supplied, by suitable legislation, it will be impossible to fill vacancies in the medical corps without lowering the present standard of examination, a resort which, if adopted, would leave us distinctly outclassed by the medical corps of the armies of all other civilized countries." The defects in the organization of the medical department can be remedied only by Congress, which, unfortunately, does not appear to regard the health and lives of our soldiers as a matter of very great importance.

RELATION OF THE HEIGHT OF THE ARCH TO THE FUNCTIONS OF THE FOOT.

By flat foot we ordinarily mean a condition characterized by functional disturbances of the foot and by pain referred to its inner border. Inasmuch as this affection is dependent upon a weakened, injured arch, and not upon its lowness, and as a true flat foot is not necessarily present, the term weak foot, as used by Whitman, is a far better one. It is still the common opinion that the height of the longitudinal arch is of value in estimating the strength and usefulness of the foot, but some statistics by F. Hoffmann in the August number of *American Medicine* prove this view to be wrong. He studied the relationship between the height of the longitudinal arch and the functions of the foot by obtaining impressions on smoked paper of feet that were functionally normal and abnormal. It is true that they do not really show the height of the arch, but only its breadth and how much of the sole comes in contact with the ground on weight-bearing. This, however, bears a relationship to the height of the arch. Comparison of smoked imprints with plaster casts of the same feet, taken while bearing the load weight, showed that the carbon impression corresponded to the flattened area of the sole of the cast, and that there was an almost constant relation between the extent of this area and the arch height. To simplify the comparison of records he chose six types of arches, ranging from the well marked to the totally absent.

Impressions were taken of seven African negroes and 179 Filipinos who had never worn footwear, and of forty-five African negroes who had worn shoes during the last five years only; not a single one suffered from the symptoms of weak foot. Their feet showed a great variation in the height and shape of the arch, the general trend being towards a flat arch. He compared these results with 200 Caucasians and 100 American negroes wearing shoes, and having symptomless feet, and found a similar variation in the arch. The primitive and American negro presenting a smaller percentage of low arches, contrary to the general opinion, than the Caucasian, and the latter a smaller percentage than the Filipino. The feet of 560 shoe-wearing Caucasians with symptoms of a weak arch also showed a variation in the height of the arch, and did not present a much larger percentage of low arches than did the 536 symptomless feet. The histories of these show that the feet with long-standing or severe symptoms were not found oftener among the lower arch types than were those, the symptoms of which were mild and of short duration. In patients whose two feet displayed a difference as regarded both symptoms and impressions, the lower arch was found just as frequently in the strong, as in the weakened foot. It is significant that among all the non-shoewearing people Hoffmann did not find a single foot associated with the symptoms of weakness, so common in adult shoewearing feet which are weakened by the restraint the shoe exerts over function. His statistics thus prove that impression records of the longitudinal arch, commonly made by surgeons, are of no value in the diagnosis of weak foot, or so-called flat foot, as the height of the arch is no criterion for the usefulness of the foot. They furthermore show that normal feet present high, medium, and low arches in nearly the same proportions as do feet with weakened arches.

THE PURE FOOD QUESTION IN GREAT BRITAIN.

The annual meeting of the British Association of Sanitary Inspectors took place a short time ago. The meeting was distinguished by a quite remarkable speech by the man who may not inaptly be termed the silver-tongued orator of the British medical profession, Sir James Crichton-Browne. Here a short digression may be made to moralize briefly on the fact that physicians as a rule are not blessed with the rhetorical gift. England, perhaps, is particularly sterile in medical orators, although the ranks have been greatly strengthened of late years by the advent of Dr. William Osler, who, of course, neither learned nor matured his very considerable powers of expression in Great Britain.

However, all this is beside the question. Sir James Crichton-Browne, at the meeting referred to, touched upon several subjects of engrossing interest to medical men everywhere. On the subject of milk he spoke very vigorously and earnestly.

He described as the primary and permanent food question the protection of milk, which enters in a greater or less degree into the diet of a vast majority of the population, and forms the almost exclusive food of a large proportion of its most susceptible units. Sir James stated that he was of the opinion that a complete reorganization of the whole milk trade throughout Great Britain was inevitable. There has been some awakening on the question, but proof of the lamentable apathy still prevailing was given by the statement made to the British House of Commons by Mr. Burns, to the effect that 20 per cent. of existing sanitary authorities have as yet made no regulations under the Dairy, Cowsheds, and Milkshops Order of 1883, a fact readily comprehensible when it is remembered that rural sanitary authorities are largely composed of the very persons whose actions such regulations would control.

When alluding to the slaughter-house and food-adulteration questions the speaker said that "if Chicago had its jungle, London had its dismal swamp," meaning that if the manner in which the meat business had been conducted in Chicago was deserving of the severest censure, London was not free from food scandals of a somewhat different character. In support of this statement, the report of a jam factory inspector was quoted, from which it was shown that for the manufacture of the so-called jam, fruit was used which was unsalable for other purposes.

Sir James then paid some compliments, chiefly left or back-handed ones, to the food faddists who flourish so abundantly at the present time. He asserted that he was in entire disagreement with those who advocated a purely vegetarian diet, and he was still a firm believer in the virtues of the mutton chop. On the question of food the faddists are as inconsistent as in all matters. Moderation in all things is a valuable maxim, and might be followed with advantage by those who advocate strict abstinence from flesh food.

The Treatment of Wounds of the Heart.

The number of reported cases of suture of the heart, according to a statement made before this year's German Surgical Congress by Rehn, one of the first to perform the operation, exceeds 120, with over 46 per cent. of recoveries. Fischer and Loison collected 729 cases of heart injuries without operation, and found that only about 16 per cent. of the patients survived, so that the benefits accruing from surgical intervention are apparent. Nevertheless, even at best the mortality is a terribly high one, and improvements in operative technique and after-treatment would undoubtedly reduce it still further. Most surgeons now recommend that in cases of gunshot or stab wounds, in which injury of the heart seems possible, the wound should be immediately enlarged down to the pericardium and the diagnosis be established by this exploratory exposure of the organ. This attitude is opposed by Franke (*Deutsche medizinische Wochenschrift*, September 19, 1907), who considers it much too radical, and proposes in its place that exploratory puncture of the pericardium be resorted to as a diagnostic measure. One of the chief dangers, he alleges, of injuries of this nature consists in the embarrassment of cardiac action resulting from the distention of the pericardial sac with blood. In many instances actual bleeding from the injury ceases spontaneously in the course of time, but the patient's life is jeopardized through the pressure of the accumulation in the pericardium, and, at any rate, the prompt performance of pericardial puncture will often tide over the critical period of time that must elapse before adequate assistance can be obtained and the necessary preparations for the more radical operation can be completed. Franke considers paracentesis of the pericardium to be not at all difficult, and attended by only slight risk, so that the practitioner should not hesitate to perform it when necessity requires. He prefers to enter the pericardium in the fifth interspace two to three cm. from the left sternal border. In order to be sure of avoiding the internal mammary artery, it is better to keep close to the sternal border. A thin trocar or large exploring needle may be used and can be slowly advanced somewhat diagonally toward the midline. Local anesthesia may be resorted to if necessary, though it is better not to use ethyl chloride, owing to the greater resistance frozen skin offers to the passage of the instrument and the consequent loss in tactile sensibility.

The Bacteriology of Plasters.

A recent article in the *Lancet* (September 21) refers to some results of examining plasters reported in one of the English pharmaceutical journals. Ordinary adhesive plaster from a package frequently opened contained an average of 22 colonies per square centimeter, and a specimen of soap plaster contained 20. Adhesive plaster with a rubber basis gave better results, but only fresh packages were sterile. Medicated adhesive plasters, with a lead, resin, or soap basis, were found to be not sterile; chalybeate, belladonna, and cantharides plasters containing respectively 13, 53, and 160 colonies in the same area. But medicated adhesive plasters with a rubber basis gave better results; plasters medicated with capsicum, belladonna, belladonna with aconite, and opium containing respectively 5, 31, 2, and 17 colonies to the square centimeter. These samples, with the exception of the belladonna plaster, were all newly opened, and newly opened packets of menthol and oxide of zinc plasters were found to be sterile. An examination of a number of "court plasters" disclosed a worse state of things. A sample of isinglass plaster stored in a tin that had been fully exposed contained 341 colonies to the same area. The various organisms found in these examinations comprised *Staphylococcus pyogenes aureus, Streptococcus pyogenes albus, Bacillus murisepticus, Bacillus pyocyaneus,* and others. Such an array of infecting agents makes one pause. The observations made showed, however, that the addition of an antiseptic substance is an efficient method of sterilization. Types of such antiseptics are salicylate of methyl, thymol, alcohol, iodol, etc. The ideal plaster medium appears to be the rubber basis made from pure Para rubber. It mixes well with various medicinal agents, is free from irritation, and is strongly adhesive. It should always be sold on reels so as to expose the smallest possible surface to the air.

The Surgical Treatment of Emphysema.

The theory in regard to the etiology of emphysema advanced many years ago by W. A. Freund appears to be receiving confirmation by the results of some surgical operations recently performed. Freund has maintained that in many cases of alveolar emphysema a congenital or acquired abnormality of

the upper thoracic opening is at fault, usually taking the form of undue rigidity of the upper ribs, particularly the first. An interesting substantiation of this view is afforded by the fact that the operation of resection of the costal cartilages of the upper ribs has produced very great relief in three cases reported respectively by Krauss and Hildebrand, Moser and Bramann, and Pässler and Seidel. The latter authors (*Münchener medicinische Wochenschrift*, September 17, 1907) speak very favorably of the possibilities of the procedure, and describe at full length the technique of the operation, which is said not to be difficult, even in the case of the first rib. The increase in mobility of the thorax, and the consequent return to the thoracic type of breathing, is said to be very striking, and great relief to the dyspnea is afforded, even though the operation is performed only on a single side. For the present the authors recommend that the operation be carried out only in more or less uncomplicated cases of alveolar emphysema, and that secondary complications, such as chronic bronchitis and cardiac insufficiency, be regarded as contraindications. The ease with which the operative details can be mastered leads the authors to consider that a practical application of Freund's view that apical tuberculosis may be induced by fixation of the upper thoracic aperture is also possible, and that operative measures planned on these lines may be found equally useful in dealing with this disease.

News of the Week.

The Harvey Society.—The program of the Harvey Society course of lectures for the coming year is as follows: October 26, Prof. E. O. Jordan, University of Chicago, "The Problems of Sanitation;" November 16, Prof. James Ewing, Cornell University, "Etiology of Tumors;" November 30, Prof. D. L. Edsall, University of Pennsylvania, "The Bearing of Metabolism studies on Clinical Medicine;" January 11, Prof. Ernest H. Starling, University of London, "The Chemical Control of the Body;" January 25, Prof. George W. Crile, Western Reserve University, "Shock;" February 8, Prof. Joseph Jastrow, University of Wisconsin, "Subconsciousness;" February 22, Prof. Otto Folin, Harvard University, "Problems of Chemistry in Hospital Practice;" March 7, Prof. Ross G. Harrison, Yale University, "Embryonic Transplantation and the Development of the Nervous System;" April 11, Prof. E. A. Schäfer, University of Edinburgh, "Artificial Respiration in Man." The lectures are given under the patronage of the New York Academy of Medicine, and are held at the Academy Building on Saturday evenings at 8:30 o'clock. They are intended for the medical profession, and all interested are cordially invited to attend.

To Legalize Sale of Skimmed Milk.—In order to answer some of the objections made by those opposed to the measures under way compelling milk producers to exercise greater regard for sanitary requirements, especially the one that the increased cost of production under the new regulations would either drive the small dairy out of business, or else would raise the selling price of the milk, the Milk Commission appointed by Mayor McClellan has decided to recommend that the sale of skimmed milk be legalized. It is estimated that 100,000 quarts of skimmed milk are at present disposed of as casein to glue and paint manufacturers at the rate of about a cent a gallon in spite of the fact that the food value of skimmed milk is very high. Formerly, when the cream was separated by the gravity method, the length of time necessary before the skimmed milk was ready for the market rendered its sale unsafe, but now under the universal use of centrifugal separators it is obtained without delay, and danger from that source is removed.

Child Suicide in Germany.—The increasing frequency of self-destruction among school children continues to attract attention in Germany, and the Ministry of Education has ordered an investigation of the causes of the situation. Statistics of such suicides show that in the twenty-one years, 1883-1903, there were 1,125 suicides of pupils of the gymnasiums and common schools. By far the greater number of such suicides were of children under 15 years old, the average yearly number for these alone reaching almost forty-two. Less than one-fifth of these were girls. The greater frequency of suicides below 15 years, however, was due wholly to the fact that the pupils below that age so far outnumber those above. As a matter of fact, suicides above 15 years are four times more frequent—reckoned as a percentage of the total number of pupils—than below that age. The official statistics do not give the causes of the suicides, except in 284 cases. The causes given for pupils of the lower schools were fear of punishment, mental derangement, and harsh treatment by parents, relatives, or teachers. In the higher schools the causes were dread of examinations, wounded self-esteem, mental derangement, fear of punishment, love affairs, and melancholia. Not less than 28 per cent. of the suicides were of children whose parents were epileptics, drunkards, or mentally unsound. In more than 48 per cent. of the cases it was found that the character peculiarities of the pupils rendered it difficult for them to accommodate themselves to the rules and regulations of the schools. The German system of education and of maintaining discipline is notorious for its severity, and it would appear that some of the reasons leading the school children to such depths of despondency could easily be eliminated.

Medical Fees in France.—The local medical association of Charenton, a suburb of Paris, created widespread excitement at a meeting on October 2 by announcing that in future the fees for medical attendance would be increased and determined on a sliding scale according to the social condition of the patients. Workmen would be charged three francs, as usual; tradesmen, well-to-do employers, small landholders, clerks, four francs; large manufacturers, merchants, and rich landholders, five francs, during the day. Between 7 and 10 in the evening and Sunday and holiday afternoons the prices would be doubled. From 10 in the evening until 7 in the morning the price would be 10 francs.

A New Deposit of Radium?—A Swiss newspaper is authority for the statement that Prof Joly, in examining specimens of the strata collected from the borings for the Simplon tunnel found rich traces of radium, indicating large deposits of the mineral. The presence of the radium, he believed, accounted for the unusual heat experienced in constructing the tunnel.

A Laboratory of Animal Psychology.—After years of delay, Prof. Hachet Souplet of Paris has succeeded in obtaining the sanction of the Minister of Public Instruction for the creation of a laboratory of animal psychology to be established in connection with the Natural History Museum for

the purpose of investigating the mortality of animals.

Flies as Carriers of Infection.—The Health Committee of Liverpool is reported as attributing the recent high morbidity in that city among infants and children to the unusually large number of flies that appeared during the warm weather and contributed to the contamination of milk and other foods.

Higher Death Rate for New York State.—According to the Bulletin of the State Department of Health, during August 13,420 deaths were registered in New York State. This gives an annual rate of 19.6 per 1,000, an increase over that for the corresponding month last year of 1.4 per 1,000.

Epidemic of Rabies in Pennsylvania.—As the result of an epidemic of rabies in Chester County, Pennsylvania, it has been necessary to kill 154 dogs, 25 cows, and 10 horses. Hydrophobia has now received official sanction, for the newspapers state that as the result of experiments undertaken at Bethesda, Md., in order to put a quietus on those who maintain that it is an imaginary ailment, the Department of Agriculture has announced that hydrophobia exists and is a real disease.

Yellow Fever in Cuba.—Several new cases and one death are reported from Los Palos, Havana province.

Plague in San Francisco.—Reports from health officers show that there are over fifty undoubted cases of plague in San Francisco and about thirty suspected cases under observation. Twenty deaths have been recorded so far.

Cholera in the Far East.—Cholera is spreading throughout Korea, and the entire district through which the Chinese Eastern Railroad runs has been officially declared likely to suffer from a widespread epidemic.

Smallpox in Chicago.—The first case of smallpox in Chicago since July 21 occurred September 20, the patient having come from Montana and never having been vaccinated.

Bequest to the Presbyterian Hospital.—By the will of the late D. Willis James, who died on September 13, each of the following institutions is to receive $100,000: Columbia, Yale, Amherst, Cooper Union, Hampton Institute, the Children's Aid Society of New York, the American Board of Foreign Missions, the Cathedral of St. John the Divine, the Union Theological Seminary, and the Presbyterian Hospital.

International Association of Stomatology.—The organization of the International Association of Stomatology, which took place at Paris, August 6 and 7, at the time of the First French Congress of Stomatology, was very successfully consummated. The officers chosen were the following: *Honorary Presidents,* Drs. Eugene S. Talbot, Chicago, and L. Cruet, Paris; *President,* Dr. Jos. von Arkovy, Budapest; *Vice-Presidents,* Drs. C. Redard, Geneva, C. Platschick, Milan, Otto Zsigmondy, Vienna, and Johan Rygge, Christiania; *Secretary-General,* Dr. H. Allaeys, Antwerp; *Secretaries,* Drs. J. Sim Wallace, London, J. Breitbach, Dresden, and D. Nicolescu, Bucarest; *Treasurer,* Dr. F. A. Meyer, Amsterdam. A consulting committee, composed of a member from each represented country, was also appointed. The American member of this committee is Dr. G. V. I. Brown, Milwaukee. The next meeting of the International Association of Stomatology will take place at Budapest, August, 1909, at the time of the XVI. International Medical Congress, which Congress will have a Section on Stomatology open to all medical graduates.

International Congress on Tuberculosis.—The preliminary announcement of the International Congress on Tuberculosis, which is to meet in Washington, D. C., next fall at the invitation of the National Association for the Study and Prevention of Tuberculosis, has been issued in the form of a pamphlet written in English, French, German, and Spanish. The officers of this special committee on the congress appointed by the National Association are as follows: *Chairman,* Dr. Lawrence F. Flick of Philadelphia; *Secretary,* Dr. Joseph Walsh of Philadelphia; *Treasurer,* Mr. Henry Phipps of New York; *Secretary-General,* Dr. John S. Fulton, 810 Colorado Building, Washington, D. C. Seven of the governmental departments have signified their intention of participating in the International Congress, and have taken measures to secure the necessary appropriations. Most of the State governors have also taken official action in regard to the congress. The congress will be divided into the following seven sections: Pathology and Bacteriology, President, Dr. William H. Welch, Baltimore; Clinical Study and Therapy of Tuberculosis; Sanatoria, Hospitals, and Dispensaries, President, Dr. Vincent Y. Bowditch, Boston; Surgery and Orthopedics, President, Dr. W. J. Mayo, Rochester, Minn.; Tuberculosis in Children, President, Dr. Abraham Jacobi, New York; Hygienic, Social, Industrial, and Economic Aspects of Tuberculosis, President, Mr. Edward T. Devine, New York; State and Municipal Control of Tuberculosis, President, Surgeon-General Walter Wyman, Washington, D. C.; Tuberculosis in Animals and Its Relations to Man, President, Dr. Leonard Pearson, Philadelphia. The section work of the Congress will be done during the week September 28 to October 3. During this period there will be two general meetings, and during the three weeks from September 21 to October 12 a tuberculosis exhibition will be open, and special lectures will be given. Three prizes of $1,000 each and several smaller prizes are offered in connection with the exhibition. Active members of the congress pay a fee of five dollars and receive a full set of the published transactions. Associate members pay two dollars and do not receive the transactions or enjoy all the privileges of active members.

The Southern Medical Society.—At the meeting of this organization held in Birmingham, Ala., on September 27, Atlanta was selected for the next place of meeting, and officers were elected as follows: *President,* Dr. B. L. Wyman of Birmingham; *Vice-Presidents,* Dr. W. P. McAdory, Alabama, Dr. H. M. Folkes, Mississippi, Dr. Frank Watson, Louisiana, Dr. J. R. Holden, Florida, Dr. R. Wallace, Tennessee, and Dr. A. L. Fowler, Georgia; *Secretary-Treasurer,* Dr. Oscar Dowling of Shreveport, La.

Chicago Physicians and Surgeons' Golf Association.—At the annual meeting of this Association, held September 22, the following officers were elected: *President,* Dr. Thomas J. Watkins; *Secretary,* Dr. George W. Webster; *Executive Committee,* Drs. John Ridlon, Wm. Allen Pusey, and Frank W. Lynch.

East Tennessee Medical Society.—Officers as follows were elected at the meeting of this organization held in Knoxville on September 28: *President,* Dr. J. W. Matthews, Johnson City; *Vice-Presidents,* Dr. D. E. Shields, Morristown, and Dr. S. C. Smith, Newport; *Secretary and Treasurer,* Dr. William Copenhaver, Bristol. The next annual meeting is to be held in Newport.

New York State Medical Society.—The annual meeting of the First District Branch of the Medical Society of the State of New York, comprising the counties of Dutchess, New York, Orange, Rockland, Putnam, and Westchester, will be held at 2:30 P.M. on Monday afternoon, October 28, at the New York Academy of Medicine.

Dr. William Oliver Moore, after an absence from the city of two years, has resumed his practice at The Sydenham.

Dr. Francis D. Patterson, surgeon to the Philadelphia Departments of Police and Fire, has resigned.

Obituary Notes.—Dr. James J. McManus of Brooklyn died on October 2, at the age of forty-nine years. He was a graduate of the Long Island College Hospital, and held a position in the Department of Health.

Dr. Henry Stiger of this city died last week of apoplexy while on a visit at Schooley's Mountain, N. J. Dr. Stiger was seventy-four years of age.

Dr. J. Howard Thurlow of Boston died suddenly on September 29. He was graduated from Harvard Medical School with the class of 1881 and had practised in the Roxbury district since that time.

Dr. R. S. B. O'Brian of Nanaimo, B. C., died on September 23, at the age of fifty-four years. He was born in Ontario, and, after graduating in medicine from McGill University, began practice in Nanaimo in 1883.

Dr. Benjamin F. Dake of Pasadena died on September 24 after a long illness. Dr. Dake was born at Portage, N. Y., in 1831, and, after graduating from the Cleveland Medical School, practised for a time in Mount Vernon, N. Y. In the early sixties he removed to Pittsburg. He retired from active practice in 1900, and since that time had made his home in Pasadena.

Dr. Benjamin S. Satterfield of Kansas City died on September 18, at the age of seventy-nine years. Dr. Satterfield was a native of Tennessee, and received his medical education in the St. Louis Medical College. He began practice in Lafayette, Mo., but after four years continued his medical studies in Philadelphia, and was graduated from the Jefferson Medical College in 1861. In 1885 he removed to Carrollton and lived there for about twelve years, at the end of which time he took up his residence in Kansas City.

Dr. Beecher W. Braley of Barre, Vt., died on September 24, at the age of fifty-four years. He received his medical degree from the University of Vermont, and previously to beginning practice in Barre had lived in Chelsea.

Dr. T. S. Collins of Burchinal, Ia., died on September 20 of heart disease, at the age of thirty-six years. He was a native of Delaware County, Ia., but had practised in Burchinal for about six years.

Dr. H. C. Hull of Crawfordsville, Ia., died after a brief illness on September 27, at the age of eighty-one years. He had practised in Crawfordsville since 1852, and leaves a son, Dr. J. H. Hull, and a grandson, Dr. H. C. Hull, both of whom are in practice in Washington, Ia.

Dr. J. Henry C. Simes of Bala, near Philadelphia, Pa., died at Cape May, N. J., on September 28, at the age of sixty-three years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1870, and subsequently spent several years abroad in study in foreign hospitals. He served as resident physician and subsequently as visiting surgeon to the Episcopal Hospital of Philadelphia. He was one of the founders of the Philadelphia Polyclinic, for many years occupant of the Chair of Venereal and Genitourinary Diseases, and later Emeritus Professor.

Correspondence.

THE BUSINESS OF MEDICINE.

To the Editor of the Medical Record:

Sir:—In the *Evening Post* of New York City, September 18, and if I remember rightly on the same date in the *New York Times*, a statement appears that at the Day of Atonement services the Rev. Joseph Silverman, Rabbi of Temple Emanuel, attacked the practitioners of medicine in the following manner: "It is not a profession; it is a trade that the doctors ply to-day. It is not the practitioner of a profession, who, with his commission to heal from on high, comes into a household and demands his fee of $500 or $1,000 before he will apply the knife to the cancer, the anesthetic, or the healing lotion to the wound. It is a trade, I say, that is plied. And such practices ought to be condemned from every pulpit, every rostrum in the land. The Government ought to step in and prevent them. It is not the art of healing, I reiterate, that is practised; it is a trade. . . ."

Remembering the tendency of newspapers to exaggeration and misrepresentation, I took occasion to write to the reverend gentleman and ask him what he really did say. He very obligingly wrote back enclosing a cutting from the *New York Times* containing a letter from a Mr. C. D. Jackson, which the rabbi said was what he really did preach in his sermon. Putting aside for the moment the statement by the rabbi that medical science is not progressing in a manner commensurate with our modern opportunities, in which statement there is ample room for discussion and dissent, Mr. Jackson's letter goes on to say that "Dr. Silverman did not charge the whole profession with greed, as Dr. Weinstein maintains, but merely referred in a single phrase to that class of doctors who demand exorbitant fees before they will operate or even relieve the patient. Such practices the rabbi justly maintained are reprehensible and should be condemned."

I write my letter to you instead of to the public prints because I believe that the subject can be better discussed in a medical journal than in a lay paper, and what I am about to write is addressed more particularly to doctors than to laymen. Of course, neither reading of the reverend gentleman's remarks is pleasant for medical ears, but I think medical men are perhaps not entirely undeserving of the criticisms which they receive. In the first place they try to combine sentiment and business, and one might as well expect oil and water to mix as sentiment and business. The practice of medicine is a business, not a profession; it is open to question if there are any genuine professions left, not even excepting the profession which the reverend critic of the medical men so ably and so well represents. The moment people work for money and for a living they engage in business, but because it is a business it does not necessarily mean that it should be a trade. Now the fact that some doctors decline to respond to a call unless they are paid beforehand is, when viewed from the sentimental side of humanity and brotherly love, a shocking and hard-hearted proceeding. It is not perhaps what the good Samaritan would have done, but then so far as the parable is concerned the good Samaritan was out two-pence in consequence of his charitable deed, nor is it recorded that the gentleman from Jericho received any benefit. It would appear that the only person who profited by the transaction was the innkeeper.

Now, I would like to ask this question: When a doctor is called by a perfect stranger to attend him or to perform an operation, why should the doctor be anathematized because he asks for his fee in advance or demands a proper guaranty that it will be paid before he takes charge of the case, and, failing such, to decline the case, if he so choose? I knew a very estimable and prominent surgeon of this city, now, alas! no more, who told me that he made it a rule to be paid for his operative work before the operation, and that on one occasion, when a personal friend of his came under his ministrations, he told him before the operation that he would trouble him for his fee. His patient remonstrated and said, "My dear Doctor X., you know me perfectly well and you know I am good for the fee," to which Dr. X. replied, "I know that; it isn't that I think you will cheat me, but it is a rule of my office and one I have adopted as a matter of self protection. I cannot make an exception in your case. To make fish of one and flesh of another would be unfair."

Now I believe that no business man would trust a stranger without having either some guarantee that the stranger was honest and solvent or that he would pay cash. Why should the doctor not be allowed a similar privilege? A great many people seem to think that a doctor is compelled to attend whenever he is called upon.

This is a mistake. It has been judicially decided that a doctor is no more bound to give his services unless he chooses to than a tradesman is bound to sell something in his shop if he does not wish to.

Now would it not be better for the medical profession to drop all the foolish cant about the extreme nobility of their profession (which is really no more noble than other professions) about their self-sacrificing and charitable attributes, and do their charities, of which God knows they do enough, quietly and unostentatiously, and give up this ridiculous habit of patting themselves on the back and calling God and man to witness that they are the noblest works of the Creator. F. R. STURGIS, M.D.

NEW YORK.

FORMALIN IN TYPHOID FEVER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The following extracts from two recent letters addressed me by Dr. Wm. G. Christian of Gordonsville, Va., seem to me of considerable interest, possibly of great value. I have suggested to Dr. Christian that he permit me to embody them in a letter to the MEDICAL RECORD—and the following paragraphs are sent you with his approval.

"For some time (four or five years) I have been thinking of the use of formaldehyde in typhoid fever, and recently I have had some cases which I think are undoubted typhoid, and have been using it. You know that we rarely see, here in Virginia, a typical case of typhoid. I have had five cases recently, of which the following is a brief outline:

"The first was seen by me about at the end of his second week, as I judged by the history. At any rate, he had a hemorrhage on the fourth day after I saw him and died five days later from repeated hemorrhages. The second, third, and fourth were seen early and each showed the gradual rise of temperature, not influenced by quinine, headache, anorexia, coated tongue, red at the edges, pointed and tremulous, dicrotic pulse up to the middle of the second week; and, in the second case, slight iliac tenderness and gurgling with moderate diarrhea of a yellow or grayish-yellow color. I saw no rose spots, but as these were negroes this is hardly remarkable. The fourth patient had nose-bleed and has since had a slight intestinal hemorrhage. The second case recovered and was dismissed about three weeks ago. During this case I did not have the Widal outfit. In the other three I used this test and got a distinct grayish deposit in the bottom of the test tube in each instance; but I am afraid I always got some blood corpuscles in my serum. This was due to the very imperfect collecting tubes, making it most difficult to get a sufficient quantity of serum to separate the clot entirely.

"Now as to the formalin. I used it in each case. The second recovered promptly at the end of three and a half weeks and never had any bad symptoms. I mean there was no meteorism, delirium, subsultus, or any symptom of the typhoid state. The third and fourth did the same thing. The fifth showed marked but not profound stupor after the formalin had been used about ten days. I stopped it for forty-eight hours and the stupor disappeared. I then commenced to use it again and to-day, the third day since its resumption, find him delirious and with a slight tendency to stupor. This is the sixteenth day of his sickness. His pulse is now 120, temperature 102.6°, respiration 30. I forgot to say he is thirteen years old. His temperature had been steadily about 104° to 105° for a week prior to to-day and pulse 130 to 140. All these cases have shown a gradual decline in temperature beginning on the sixteenth to the eighteenth day. Of course, I have used bathing, attention to diet, etc., just as if I were not using the formalin.

"The questions are: (1) Are these cases typhoid fever? and (2), if so, does the formalin do any good? My idea has always been that the bacillus typhosus had nothing to do with the production of the typhoid condition, but that the latter was the result of a mixed infection, was a septicemia, in fact, the organisms being introduced through the typhoid ulcers, which act as any other solution of continuity would do in introducing septic infection. I do not believe that formadlehyde or any other antiseptic would affect the course of typhoid fever, even if you could douche out the entire intestinal canal as you do an open wound; but I have thought it possible that we could prevent the septicemia by giving intestinal antiseptics throughout the disease. I selected formalin because it seems to be germicidal in the gaseous form in such attenuated strength; because I found it to volatilize so rapidly and thoroughly impregnate the air when moderately heated; because it was nearly nonpoisonous; and because it is eliminated through the kidneys, and I thought, might sterilize the urine—possibly the feces also. Of course, it is difficult to administer. I have found the following prescription the easiest to take:

℞ Oil of turpentine ..... gtt. lxiv.
Formalin ..... gtt. cxxviii.
Menthol ..... gr. v.
Alcohol ..... ʒii.
Pulv. gum arabic ..... ʒiv.
Dist. water ..... qs. ad. ʒiv.
M. Liq. Teaspoonful in 2 to 4 ounces of water every 4 hours.

"The turpentine I use because I have found it to have a good effect in relieving tympany. The menthol was put in because I saw that it rendered the formalin less irritating. Without it, my patients suffered from laryngeal irritation and coughing.

"Do you think the plan worth trying in hospital work, where accurate tests can be made? With one exception my cases are all negroes and of course get very imperfect nursing. The one white patient has been rational and perfectly comfortable throughout his attack. I do not believe formalin shortens a case of typhoid, so far as the typhoid fever is concerned; but I am inclined to think the unmixed typhoid is not a disease of much over two weeks' duration. I do not think the treatment does any good unless begun early. I find very copious dilution with water necessary to prevent vomiting. One of my patients had to take a large glassful of water with each dose. I saw Dr. Harper (Professor of Chemistry at Fort Worth) a few days ago and asked him how much formaldehyde gas a four-drop dose would probably place in the intestinal canal. He said about 1-20,000."

NEW YORK.

GERM-ENCRUSTED BREAD.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Imagine that you have seen a loaf of bread through the process in a bakery, and that it is now ready for the delivery wagon—and driver. The driver's employment involves the care of stable and horse. He is on hand early, and cleans out the stable and then curries and grooms the horse. And if a bacteriologist ever goes germ-hunting he can find the richest of all fields in the dust and dirt scraped from the hide of a city horse. There never was such a culture bed as the warm, sweaty, hair-protected hide of a horse to cultivate germs and allow them to multiply. So the driver curries on, filling the air with germs and fairly dusting or abundantly peppering himself all over with them, making his coat a veritable germ storehouse. And the horse curried, he is harnessed and then put into the wagon, very likely with only a grated open back; and, all being in readiness, the driver, with arms full of fresh, sweet bread, hugs the loaves to his bosom, as if he were cuddling a favorite child, and throws them into the dusty bread-box in the wagon. And, armful after armful, he lugs and hugs, and if the germs are smart, and know a good thing when they see it, they desert his coat by the millions and fairly encrust the new, warm, moist culture ground, where, within ideal surroundings, they can thrive, increase, multiply, and depopulate the earth. And then away goes the driver, stopping at houses and hugging the loaves to his bosom. How that driver does love that bread, the way he hugs it all the time, and what a time the germs are having in a migratory sense! A crusty loaf of fresh bread is a much better lodging than the dry meshes of a man's coat. And, it being, perhaps, a windy March day, the bread has cooled nicely in the well-ventilated wagon and collected a few germs from the dusty air of the street that the horse's hide failed to appropriate.

And then the driver, loath to quit hugging that sweet bread, lays it down outside the area window or on an open hall basement table, or in an elevator shaft—anywhere, in fact—and if there are any germs about he can't see them. So the bread, that was so carefully guarded and protected from dirt and germs by the careful, painfully clean baker has had the devil's own germ-spell between the bakeshop and the table. Much like the French convent girl, made a recluse, and then given her diploma and turned loose into the world, after going through a mariage de convenance. The driver may be faulty as to germs, but think of the vicissitudes, in a germ sense, of a loaf of bread left at the grocer's, to be put on the shelf or counter and sold to a customer! What may, can, and does happen to that loaf, speaking in a germ sense, no one short of a bacteriologist with a microscope of the highest power can properly tell. The Board of Health inspector will chase a suspicious can of milk across half the town because of suspected germs, but he will pass by several

millions of quite as dangerous ones nestling snugly within the interstices of the crust of thousands of loaves of bread in the drivers' wagons of the bakeries.

And where is the remedy? How can this menacing situation be met, and the cleanly efforts of the baker within his building, but not without, be made to count? Waxed paper is impervious to moisture, air, germs, or infection of any kind. It is cheap. If each loaf of bread, when coming from the oven, were inclosed and sealed in a wrapper of waxed paper, then the bread would deserve a place in spotless and germless town—be free of all contamination from dirty hands and flirtier, germ-infested clothes. The infinitesimal cost of such absolute protection and its absolute sanitary advantages should prompt any physician, not only to demand his own bread wrapped in a waxed paper germ-proof wrapper, but he should instruct his patients accordingly. And all this being so, when typhoid develops in a family, the doctor, if the bread eaten were delivered so sealed up, would guess the source of the germs that made the trouble as coming from some other source than the bread, that picked the germ up from somewhere between the bakery and the dining table.

CHARLES CRISTADORO.

POINT LOMA, CAL.

OCCLUSION OF THE POSTERIOR NARES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I see in the MEDICAL RECORD of September 7 an article on congenital occlusion of the posterior nares by Dr. J. E. Mackenty. In a paper read before the Missouri State Medical Association in 1898 I reported two cases treated by me in 1894 and 1897. The operation was performed by means of the dental engine, and my case of 1874 was the first instance of the employment of the dental engine for this purpose. The young woman upon whom I operated then is now living in this city, and the result of the operation has been all that could be desired. I was at that time indebted to Dr. Alvin A. Hubbell of Buffalo, who wrote an article on the subject which was published in the Buffalo *Medical and Surgical Journal* for December, 1880.

The first reference to this trouble was by A. W. Otts of Breslau, in the "Compendium of Human and Comparative Pathological Anatomy," English translation, 1831, p. 181. Karl Emmerts reported a case in the Lehrbuch der Chirurgie, Vol. 2, p. 355, 1853. The next case reported was by Luschka in the *Archiv. für pathologische Anatomie*, Vol. XVIII., 1859. Betol reported a case in the *Archives de Toxicologie*, September, 1876. I notice Mackenty makes the same error as Mackenzie in calling this author Betts. In the second edition of his work on "Diseases of the Throat and Nasal Passages," 1870, p. 385, Solis Cohen reports another case. Morton of Philadelphia reported a case in 1880 (Surgery of the Pennsylvania Hospital, 1880, p. 333).

In 1881 Oren D. Pomeroy reported a case at the meeting of the Medical Society of the State of New York (see Transactions, 1881, p. 200), and in the same year R. C. Brandeis reported another case in the MEDICAL RECORD for November 12. T. B. Wilkinson records another instance in the *North Carolina Medical Journal* for June, 1882. And finally, W. E. Casselberry of Chicago reports one in the *Journal of the American Medical Association* of August 8, 1885.

At the time my article was written there were only 19 cases on record, including the two I reported. It seems to be becoming more fashionable, as the increase from 19 cases in 1898 to 100 in 1907 testifies. The greater number of these cases were found at autopsy and had apparently never been treated.

J. RUTH FRITTS, M.D.

MEXICO, MO.

FECUNDITY IN THE AGED.

TO THE EDITOR OF THE MEDICAL RECORD:

Mrs. Catherine Sherwood at [illegible] of life bore quadruplets to triplets, who were named respectively, Frank [illegible], and Frederick. They all became successful in [illegible] to be more than seventy years old.

All [illegible] of the brothers that [illegible] Charleston, S. C., [illegible] all went into the same [illegible] shop and lay [illegible] down in the early morning [illegible] and [illegible] in the evening. And the baker said that he never [illegible] whose beard grew so rapidly as theirs did.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INSANITY—MEDICAL INSPECTION OF SCHOLARS—OFFICIAL SCIENTIFIC RESEARCHES—SANITARY INSPECTOR'S CONGRESS—DISEASE IN A MENAGERIE—DEATH FROM CARBOLIC ACID.

LONDON, September 21, 1907.

THE sixty-first report of the Commissioners in Lunacy has appeared and as usual set the newspapers commenting on the increase of insanity and amazing or alarming their readers according to the views they suggest. A sensational statistician has been calculating the date at which the nation will be composed only of lunatics, but I have not met anyone who is seriously scared at the prospect, though one has asked who will then take charge of us, for no nation is likely to desire to annex a population incapable of providing for its sustenance. If the destiny of the race is to disappear as demented, perhaps it will leave some branch which will care for it during its last stages. The figures of the blue book in question do not seem so alarming as the scare-mongers would like us to believe. There were under care in January 123,088 insane persons, a number exceeding that of 1906 by 2,009. This increase may be contrasted with that of 2,150 for 1905, of 2,630 for 1904, and of 3,235 for 1903. The increase for 1906 was really less by 453 than the annual average of the decennium. The total number of the insane stands, according to the figures of this report, in the proportion of 1 to 282 of the estimated population, or 35.48 per 10,000, and this gives an increase on the ratio of the preceding year of 0.48 per cent. But the actual numerical increase equals 1.64 per cent. The increase in the decennium amounts to 12.1 per cent. London and Middlesex show an unenviable increase in pauper lunatics. Grave as the figures appear at first sight, there are factors which, the Commissioners admit, render it impossible to decide whether the proportion of actual occurring insanity is increasing. They again point out that more care is taken to segregate mild cases and that fitness for detention is recognized as showing need for treatment as much for protection for himself as for the community. Moreover, aged persons are more often certified and treated in asylums; these as well as others were left almost entirely outside a generation ago. In fact, every practitioner must be aware that a great number of cases of defectives are now being notified that would not have been sent to asylums a decade or so since. Further, the rise in the numbers of "first attack" encourages the belief that treatment is more successful than formerly—a belief strengthened by a corresponding decrease in cases which are not first attacks. The great majority of the discharged left the asylums within two years of their admission. Altogether the statistics attainable, though they point to increase, are, in the commissioner's view, "too open to qualification to justify such a conclusion."

The Board of Education has lost no time in setting about the duties imposed on it by the new act in regard to the medical inspection of school children. The legislature having decided that such inspection shall be compulsory and given fresh powers to local education authorities, the duties of the central board will, to a great extent, consist in advising and supervising as to the manner and degree in which this medical inspection should be carried out. Directions will have to be given regarding the frequency and methods of inspection in particular areas, and proposals under the act by different authorities as to promoting the physical welfare of the scholars will have to be considered. Further, the board announces that it will collect and collate records and reports made by the authorities and issue an official annual report on the subject. With so full a program it is obvious that the board is well advised in establishing a new medical department, and that on a broad basis of public health, and so to organize its work as to utilize as far as possible the means and methods of sanitary administration already existing, and to develop or supplement them as may prove to be desirable rather than to bring into existence competing agencies when this can be avoided. These decisions will undoubtedly be approved by those who have worked so assiduously to secure medical inspection, and if only the central board will give a free hand to the new medical department we may expect important results. This new department is not yet complete, but as I mentioned last week, two appointments have already been made. Both the gentlemen selected are well known sanitarians and competent to advise the board on all questions of public health. Further appointments are promised, as well as a circular to local educational authorities to guide them in their new duties concerning the medical inspection of the school children. All this looks well on paper, but those who compare it with what has gone before sympathize with the misgivings expressed by those behind

the scenes. The doubt cannot be suppressed that the permanent officials will not, if they can help it, give the free hand to the medical staff which is essential for success. Great disappointment is felt that the chief adviser of the London Education Committee, who has the greatest experience in school hygiene, was not offered the position of chief medical officer. It is even whispered that the permanent secretary had promised it to the friends and admirers of his work, but has added another breach of faith to the long list of this government's record. The public as well as the profession is dissatisfied, though, as I said above, there is no question that both those appointed are well qualified for the work—if only they insist on a free hand.

The official scientific researches "concerning the causes and processes of disease," which I told you in my last have been authorized by the local Government Board, are the following: 1. Further study by Dr. Sidney Martin, F.R.S., of the chemical products of pathogenic bacteria. 2. Bacteriological investigation by Dr. F. W. Andrewes of the air of sewers and drains. 3. Observation by Dr. W. G. Savage of the bacteriology of "garget" and maladies of the udder, or teats of milch cows, and of possible relation of sore throat in the human subject to pathological conditions in those organs. Also investigation by him of paratyphoid fever and its microbic cause. 4. Joint investigation by Drs. M. H. Gordon and T. J. Horder of the life processes of the meningococcus with a view to means of combating cerebrospinal fever.

The investigation of ankylostomiasis, which I announced last week, is entrusted by the Royal Commission on Mines to Dr. A. E. Boycott. The question of whether a standard of ventilation in mines should be laid down has induced the commission to appoint Mr. John Cadman assistant inspector of mines to make a series of observations and tests of the air in mines.

The Sanitary Inspector's conference opened on Tuesday with a trenchant address by Sir J. Crichton-Browne. He urged more severe dealing with adulteration, but even that was not enough, for suicide as well as assassination must be prevented and home-made foods required strict surveillance. The fashionable fads and follies of the hour were in the nature of deprivation, though it was once thought creditable to be a good trencherman. Now dietetic asceticism had gone so far that in dread of being thought gluttons people indulged a healthy appetite in secret. After denouncing various foods he proceeded to the more dangerous drug habit, and instanced specially lozenges, which are manufactured on a large scale and sold ostensibly for coughs, but were found to indulge a vicious taste, leading too often to narcomania. He said two of them contained a minimum and six a maximum narcotic dose.

On the second day Sir Wm. Richmond, R.A., read a paper on smoke abatement on which he had spoken, he said, for so many years that every sentence he now used seemed a platitude. Westminster Abbey and other buildings were fast decaying from the effect of coal smoke, but Parliament let the evil go on. Mr. Nicholson followed with a paper in which he estimated one-third of the coal used in this country might be saved by consuming the smoke. We should not recognize a smokeless London!

An outbreak of a disease, evidently of an infective nature, having carried off several wild animals in the Blackpool menagerie, Professor Annett of the Liverpool University undertook an investigation of the pathology. He found a bacillus of the type recognized in animal diseases, such as swine fever, influenza, pink eye of horses, distemper in dogs and cats, etc. The postmortem appearances were such as are commonly met with in such infections.

On Monday a coroner's jury gave a verdict of accidental death in a very unusual poisoning case. A man was found in an unconscious condition and carried to his home. A doctor was called in to whom the man on regaining consciousness said he was carrying a quart bottle of carbolic acid in his pocket. It broke on the way and he wiped the acid from his body with his handkerchief. He rode some distance in a 'bus and remembered nothing after it. The doctor gave evidence that the man's condition was consistent with his statement. The acid had been absorbed from the surface and he died of carbolic poisoning.

A report has gained currency that a French patent has been obtained or sought for preserving meat by sulphurous acid. Several correspondents say they have used this plan. One says he was shown it forty years ago and has since used it. Another describes his simple process by which he has exposed beef to the air without apparent change since he treated it in 1870. He cut it into strips about 6x2 inches, hung them in a glass jar, attached a small thimble containing sulphur by a wire to the cork, lit the sulphur, closed the jar, and let the sulphur burn until the oxygen in the jar was consumed and so it went out.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CHOLERA—TROPICAL HEMOPTYSIS—MALARIA—INSANITY—SUPPRESSION OF SMALLPOX BY VACCINATION—THE PURE FOOD ACT IN THE PHILIPPINES.

MANILA, P. I., August 23, 1907.

THE cholera, of which mention has been made, which appeared in Manila during the latter part of July and the beginning of August, seems to have made no progress, the last case having been reported August 9, 1907, and a total of only five cases having occurred in the City of Manila. The outbreak of this disease at Carigara, Leyte, also seems to have been checked, the number of deaths being reduced from three per day to about one death in two days.

During the year there were seventeen cases of *Paragonimus westermanii* infection reported as having occurred in Bilibid prison. Of these cases eight were fatal, the diagnosis having been made at the autopsy. It is generally believed by medical men in the city that many cases which are now diagnosed as tubercle of the lungs, and find their way into the mortality reports under this heading, are, in reality, fluke infections.

During the year twenty-three deaths less from malaria were reported in the City of Manila than for the previous year, the total number being 173. On account of the fact that a great majority of these diagnoses are not confirmed microscopically, it is exceedingly doubtful as to whether there were actually that number of deaths from this disease in the city. The anopheles are not common in Manila, and it is believed that the majority of cases of malaria that are reported are contracted outside of the city. In the provinces, particularly in Albay and the Camarines, the disease has been very much less common than heretofore, which fact can be ascribed, perhaps, to the free distribution of enormous quantities of quinine issued to the indigent poor of these districts.

In connection with insanity statistics, it is interesting to observe that while in the United States 1 out of every 466, and in Great Britain 1 out of every 304 is insane, in the Philippines only one person out of every 1,667 is classified as being insane. These figures are significant in view of the fact that consanguineous marriages are generally thought to be very common in the Philippines, and, since marriages of this kind have been said to be one of the principal causes of insanity, it is noteworthy that it does not appear to be operative to any large extent here. In the entire Philippine Islands there are 3,449 insane persons reported, and of this number less than 300 are cared for in asylums, the others either being at large or kept in private houses by relatives or friends.

Owing to the liberal provision made by the Commission during the past year, it has been possible, by systematic methods, to vaccinate 2,022,380 persons, which is an increase of 1,072,255 over the previous year. In addition, there were 50,000 persons vaccinated by local officials in municipalities where the disease made its appearance. These figures probably represent a greater number of vaccinations, in proportion to the number of inhabitants, than have ever before been done in a similar period of time; in fact, it is questionable whether in any country more than 2,000,000 have been vaccinated in any one year. The complete cessation of deaths from smallpox in provinces where the people have been thoroughly vaccinated affords another striking proof of the efficacy of vaccination, and if any further evidence were required as to its effectiveness in suppressing smallpox, the Philippine Islands could afford instances innumerable. In seven provinces, where heretofore there have been 6,000 deaths annually from smallpox since time immemorial, there has not been a single death reported for over a year, and when it is remembered that the vaccination of these provinces was completed a little over a year ago, the significance of this will be apparent.

Last November the Governor-General of the Philippine Islands called attention to the Pure Food Act, which was passed by Congress, June 30, 1906, in a proclamation, and named the officials who should enforce its provisions. However, on the recommendation of the Attorney-General, who held that on account of the difference between the judiciary systems of the United States and the Philippines the legal machinery for enforcing the act here was not adequate, a new act was drafted, embodying all of the act of Congress and making only such corrections and additions as would adapt it to the Philippines, and was passed May 8, 1907, to go into effect July 1, 1907. The act will be enforced by the Bureau of Health. Some little delay in enforcing the act is experienced on account of the time required to procure chemists who are competent to make the necessary analyses.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 26, 1907.

Separate Nursing and Isolation in Typhoid Fever.—E. P. Joslin and C. L. Overlander believe the time has come when typhoid patients should be treated in separate wards in our hospitals, with their own attendants, who should not mingle with other patients. They note that the present methods of mixing them with other diseases leads to a spread of the infection, quoting Schuder to the effect that three and three-tenths per cent. of all typhoids are the result of hospital infection. Nurses frequently contract the disease. Statistics collected from six Boston institutions over a period of four years and embracing nearly 3,000 cases of typhoid show that for every 114 cases treated one nurse came down with the disease. They declare that, considering the dangers nurses now run, under no circumstances should a "probationer" ever come in contact with a typhoid case. Typhoid nurses should not be overworked and the greatest pains should be paid to the health of night attendants. In all the American hospitals there are enough fever cases to insure the proper training of nurses. They deny that it is in any respect harder to care for several typhoids at once than for both typhoids and nontyphoids. On the contrary, it is far simpler to do strictly typhoid or nontyphoid nursing. The typhoid utensils will all be found in one place, supplies will be made and procured in bulk and thus many duplicate steps saved. The concentration plan of nursing typhoids should easily lessen by one-half the number of days of a nurse's exposure to the disease. Separate nursing eliminates the chief danger to which other patients are exposed, as the "go-betweens" are eliminated. A given case may harm a fellow-typhoid from proximity, but the danger is far less than that of giving the disease to a neighbor weakened by some other malady. Isolation of typhoids was made compulsory in Germany two years ago. The knowledge of a nurse that she is detailed for strictly typhoid duty leads her to be far more careful as to precautions for her own protection.

New York Medical Journal, September 28, 1907.

How Far May the General Practitioner Employ and Benefit from Laboratory Methods of Diagnosis?—R. N. Wilson writes from the standpoint of an internist. There is no condition known in clinical medicine that can be completely and exclusively diagnosticated by means of either old or new devising. Wisdom makes a judicious combination of the two. No graduate of recent date, however, fails to understand the value of modern laboratory methods. Probably no physician to-day really believes that a patient has been properly and thoroughly examined until every excretion and secretion has been studied, also the blood and the combined results of these studies compared and contrasted with the physical examination. The immediate practical question is, To what extent are these methods available to the general practitioner? He himself may not have the time for this work, but there are others who have and their services are easily available. The country physician can easily take a course in methods of laboratory analysis and thus be able himself to solve the crucial problems in the majority of his cases. Every physician should have at least a good microscope and learn to stain for tubercle bacilli. The younger practitioner, working along these lines for an older man, should insist on sending in his own bills for services rendered. The older and the younger man should work in harmony and thus both are stimulated. The work of the one serves as a corrective for the work of the other, and the welfare of the patient is immeasurably subserved by this combination of effort.

Aural Vertigo and Menière's Syndrome.—Three cases are related by W. A. Wells, who says that the term "Menière's" disease ought to be abandoned and Menière's "syndrome" substituted therefor. In his original case, reported in 1805, of a man attacked with intense vertigo, nausea, vomiting, and tinnitus, followed by complete deafness, it was found that a hemorrhagic exudation had occurred in the semicircular canal. But in many cases since reported with the same symptomatology, a variety of lesion has been observed. In one of the author's cases there was present only middle-ear inflammation, with slight secondary labyrinthine inflammation. It illustrated the apoplectiform type of aural vertigo, with the usual prodromal symptoms relieved by the paroxysm, and the occurrence of slight vertigo in the intervals on contracting cold. In a second case the labyrinthine involvement was predominant, and was evidently due to a vasomotor disturbance. Instead, however, of chilly sensations and cold sweat during the attack, there was flushing, feverishness, and an anesthesia of the auricle. In a third case there was a history of trauma (blow on the ear ten years previously), the attack was marked by loss of consciousness, and the trouble seemed wholly labyrinthine, the middle or internal ear not being affected. Wells believes that actual labyrinthine exudate is extremely rare in these cases. He makes some remarks on the general subject of equilibration as related to aural functions.

Chronic Myocardial Disease.—C. Schram presents a general consideration of the clinical aspects of this malady, discussing etiology, symptoms, and treatment, paying especial attention under the second heading to Cheyne-Stokes respiration, the Stokes-Adams syndrome, and angina pectoris. Concerning treatment, the author says that we must proceed along lines suggested by the realization of the following facts: (1) That we have to deal with a chronic disease capable of quiescence, possibly permanent, but ordinarily slowly progressive. (2) That the heart will never be capable of more work than the present state of its parenchyma warrants. (3) That while temporary weakness from overstrain may be amenable to treatment, any call for more work means further degeneration. (4) That it affects all the constituent tissues, the muscular fibrillæ, the circulatory, nervous, and ganglionic apparatus, the last perhaps least. (5) That it may be localized, as, for example, externally from a pericarditis, internally, from bacterial invasion, affecting perhaps the papillary muscles alone, or from an infarct or diffuse as from syphilis, lead, or phosphorus poisoning. (6) That compensatory hypertrophy does not take place as when increased resistance is to be overcome, due to valvular defect within or arteriosclerosis without. (7) That extra organic and vascular complications usually exist.

Journal of the American Medical Association, October 5, 1907.

The Pathology of Exophthalmic Goiter.—W. G. MacCallum describes in detail the anatomical conditions found in sixty cases of exophthalmic goiter of varying degrees of severity. The changes found in the thyroid were practically the same in all cases, varying only in degree and extent according to the severity of the case. They consist essentially in a great proliferation of the epithelial cells by a process of mitosis, and the change is anatomically the same that is produced in compensatory hypertrophy when we excise a portion of the normal gland, but in that case no mass of tissue in excess of the normal is produced and no symptoms result. There cannot, therefore, be a complete analogy between the two conditions, and there must be something more than the mere hypertrophy, either in the thyroid secretion, or in some other factor quite aside from the thyroid. There seem, however, to be no constant pathological conditions elsewhere, in the parathyroids, sympathetic system, central nervous system or other tissues and organs, and as we see the case improved by thyroidectomy and made worse by thyroid extract, we are almost forced to consider the overactivity of the gland at fault. There is, however, no other example of the spontaneous hypertrophy and overactivity of an organ to the damage of the rest of the body, and MacCallum suggests that there is possibly some underlying infection, such as influenza, reaching the thyroid via the pharynx and setting up a nonsuppurative inflammation, ending in hypertrophy and perverted activity. The relation of iodin to the disease is interesting, it being claimed by Brown that it aggravates the symptoms. It may also be possible that a lack of vasoconstrictor action of the sympathetic on the thyroid is a factor. It appears probable that it will be through studies of the thyroid disturbances that we will have to look for the explanation of the disorder and for its rational therapy.

Trigger Finger.—R. F. Weir describes this condition, known also as lock or snapping finger, and gives the history and theories of the disease. It is a rather rare disorder and of comparatively recent description, having been first noticed by Notta and Nelaton in 1850. It is due to tendon changes in a large proportion of all cases, the operative cases collected by Weir showing that the trigger action was due to causes situated in the tendon or its sheath in thirty-five of the forty-two tabled cases. The obstruction, moreover, when recognized was a removable one and restoration to normal function occurred when it was removed. Another important observation was that, even if the obstruction was not found, a free incision of the sheath caused disappearance of the trigger action. This occurred in two cases. As regards the causes, what has been revealed by careful examinations of removed tendon and its sheath, excluding tuberculous deposits and the changes following acute trauma, is a certain amount of circumscribed fibrous hypertrophy (tendinitis callosa circumscripta, Bergmann). The studies of Thorn and Morian strongly suggest the possibility that the larger tendon

changes are due to previous hemorrhages (traumatic) and subsequent degenerative changes in their interiors. Weir is inclined to credit the possibility of gouty or rheumatic tendencies aiding the development of thickening of the tendons from slight repeated injuries and causing interference with motion. He reports his own case, in which, though the exact cause of the trouble was not determined by the operation, complete relief followed division of the tendon sheath. He is inclined to advise simple free incision of the tendon sheath as the curative procedure for this condition. The suture of the sheath after removal of whatever obstruction may be found need not be resorted to. Care must be taken to preserve the arch of the digital sheath at the base of the first phalanx.

Spontaneous Arterial Degeneration in Rabbits.—The arterial degeneration claimed to be produced by the administration of adrenalin to rabbits has been investigated by Amy B. Miles in the Pathological Laboratory of the University of Colorado. Her experiments were performed on 61 rabbits, to which doses from 0.5 m. to 15 m. were given by hypodermic injection three times a day for periods varying from one to forty or more days. There was no constant relation apparent between the extent and frequency of the lesions found and the size and frequency of the dose or the duration of the treatment. The extensive lesions were found in a rabbit that had received only 150 m. altogether in 5 m. doses, while others receiving from four to eight times as much showed no lesions whatever. Arterial lesions were found in 17 rabbits out of the 61, a percentage of 27.86. Similar tests were made on 49 assumedly normal rabbits, with like results, lesions being found in 17 out of the 49, or in a percentage of 34.77. Allowing for some possible differences of environment, food, etc., in these latter, which were obtained from dealers, they still show that spontaneous degeneration in the vascular system of rabbits supposed to be normal is not uncommon, and suggest the possibility of a large proportion of the lesions reported in previous literature having not been due to the drugs used, but present before the experiment began. The pathological findings in the rabbits are described, and in an added note by O. P. Johnstone similar results obtained by examination of apparently normal rabbits at the University of Chicago are reported.

The Specific Nature of Opsonins.—J. McFarland and E. M. L'Engle report experiments made to test the specificity of opsonins, which would seem to be inferred from their close resemblance in nature to agglutinins, precipitins, etc. A first experiment made with staphylococcus vaccine seemed to show that its injection caused a marked alteration of the phagocytic activity toward staphylococci, though it failed to influence the activity toward tubercle bacilli, thus confirming the specific action. A second experiment, however, brought out the contradictory result that the blood of rabbits inoculated respectively with yeast and human red corpuscles became phagocytic not only to the substances with which they had been inoculated, but also exhibited a striking change in their activity toward the staphylococcus. The only explanation that suggests itself to the authors of the article is that offered by Hektoen in his study of the hemopsonins that some are specific and some only partially specific. It seems to them that what is true of the hemopsonins may also be true of bacterio-opsonins, and that the injection of yeast cells is followed by the development of a small quantity of specific opsonin for yeast cells and a considerable quantity of non-specific opsonin that acts on the staphylococcus. There are still some things to be accounted for, however, in the paradoxical reaction, such as the permanence of the staphylococcus opsonin in the case of the yeast rabbit and its decline in the case of the blood rabbit. The estimations of opsonic power were made in these experiments by both Wright's and Simon's methods. They consider that it makes little difference which is chosen, but observations that are to be compared with each other should be made by the same method.

The Lancet, September 21, 1907.

A Case of Land Scurvy.—The case reported by J. B. Dawson was that of a woman in whom the malady occurred after she had been for a prolonged period, an inpatient of a hospital and as a complication of fistula in ano. She was admitted to hospital with an unhealed fistula wound with a copious purulent discharge. A first operative attempt was made to clear the wound but its progress toward healing was unsatisfactory and in a few weeks she began to have sore mouth, swollen gums, intermittent fever, bleeding from the gums, and from the rectal wound, purpuric rash, etc. She was at once put on an anti scorbutic diet (in addition to indicated medical measures) and began to improve in every way. Associated with this general betterment, the wound condition improved, the separative power of the tissues increased, and in the course of a few weeks she was able to leave the hospital, if not cured, at least very considerably improved. The author notes three points of interest in the case. (1) The occurrence of scurvy in a patient whose food had been the same as customary among people of her class, for on special inquiry she stated that she was in the habit of taking plenty of good and fresh food. Moreover, she had been in hospital a month, where her diet was a plentiful one of milk, beef-tea, custard, jelly, and so on, before the onset of the scorbutic symptoms. (2) The possibility of the retardation of healing seen in certain forms of long-standing "callous" wounds being due to a scorbutic diathesis. (3) The possibility of the long-continued suppuration and mental distress being the cause of this diathesis, a vicious circle thus being produced.

Relation of Polymastia to Multiparous Birth.—T. Iwai has made a statistical study of this subject as affecting his countrywomen and reaches the following conclusions: (1) It is probable that there is a relation between polymastia and multiparous birth. (2) It is probable that those who have supernumerary mammary glands have a tendency to become more frequently pregnant than those who have not. (3) The fact that the instances of multiparous birth increase in women with the number of their conceptions and the development of their age coincides well with the opinions given hitherto by several eminent scholars. (4) According to my own observation the instances of multiparous birth are found more among people of the lower class, and especially among those of a low order of intelligence. A bibliography of the topic is appended.

Bombay Spirillum Fever.—A preliminary note on disease is made by F. P. Mackie, who considers the morphology of the organism, its cultivation, results of inoculation experiments, etc. It appears to be transmitted by the common bedbug, and it has been found that an immunizing serum may be prepared by passing the toxic element through the blood of monkeys. There seem to be morphological differences between the spirilla from cases of relapsing fever in America and the organism found in the Bombay cases. From the former an immunizing rat-blood serum has been prepared, and the examination of the latter confirms the dissimilarity of the two organisms. The author takes up certain details of an epidemic recently occurring in one of the Bombay hospitals.

British Medical Journal, September 21, 1907.

Bradycardia With Epileptoid Attacks.—A. E. Remmett Weaver reports the case of a woman of seventy-four years, who two or three years previously after a healthy life noted that she was losing weight and having increasing attacks of breathlessness with sinking feelings at the epigastrium. Later she was told that her heart was affected and began to have attacks of bronchitis. Still later she began to have epileptoid seizures. On examination she was found to have a pulse rate of from 26 to 33, with feeble pulse of more volume, but no thickening of the vessels. The author regards the bradycardia as due to cardiac degenerations. The veins of the neck did not show a frequency of auricular pulsation greater than the heart beat, such as are described as proofs of heart-block in Stokes-Adams disease. There was evidence of kidney disease, but absence of high vascular tension, which probably accounted for the thinness of the vessels. Cyanosis preceded the tonic epileptiform stage (which was succeeded by the clonic in the usual form), and this fact supports the view the author claims, that such epileptiform seizures are due to disturbed cerebral circulation.

An Operation for Embolus.—W. Sampson Handley reports an attempted removal by operation of an embolus lodged at the bifurcation of the abdominal aorta. There was a temporary restoration of the blood current in the femoral artery. The author regards the case as one of those pioneer failures on which ultimate success so often rests. His patient was a man of sixty-five years, in whom the embolism followed an operation for hernia. He had but little atheroma, but was emphysematous and extremely gouty. Thirty-six hours after operation the whole left lower limb was cold and no pulse could be found in the common femoral artery. A vertical incision three inches long was made over the left common femoral artery with its center at the origin of the profunda femoris. The external circumflex branch of the profunda was exposed, ligatured, and divided transversely on the proximal side of the ligature. No bleeding occurred—a fact of ill omen, since it showed that secondary thrombosis of the arteries of the limb had occurred below the point of obstruction. A flexible tube about the size of a No. 4 catheter was passed upwards through the divided proximal end of the circumflex artery into the common femoral artery. The

end of the tube was connected to an aspirator, and some soft blood clot was sucked up into the tube. No blood flowed, and the tube was withdrawn. It was decided to attempt to dislodge the obstruction by a stream of saline solution. In order to obtain better access and a freer reflux, it seemed necessary to divide as large an artery as was compatible with the subsequent maintenance of nutrition in the limb. The profunda femoris was, therefore, divided at its origin and its distal end ligatured. The abdominal aorta was compressed at the level of the umbilicus through the abdominal wall, so as to safeguard the right common iliac from obstruction. A Kelly's ureteral catheter was now introduced through the divided proximal end of the profunda artery. It was cautiously passed upwards along the common femoral, the external iliac, and the common iliac artery until, as judged by previous measurements on the skin, it had reached the bifurcation of the abdominal aorta. A forcible stream of saline was sent through the catheter, and returned freely through the divided end of the profunda. The point of the catheter was moved about within the artery, so as to detach the clot within it. Some fragments of recent clot escaped, but relaxation of the pressure on the abdominal aorta was not followed by a jet of blood. The aorta was again compressed, and the washing-out process was continued. Relaxation of the pressure on the aorta was now followed by the escape through the divided profunda of a forcible, pulsating stream of bright-red blood. An attempt was next made to clean the lumen of the superficial femoral artery. The common femoral artery was compressed. A small incision was made over the popliteal artery, and one of its branches was divided so as to provide a point of outflow for the saline solution with which the operator proposed to flush out the artery from above. The catheter was passed easily in from the divided end of the profunda downwards along the whole length of the superficial femoral artery, and almost as far as the bifurcation of the popliteal. Unfortunately, the general condition of the patient, desperate to begin with, forbade further persistence. The catheter was withdrawn, and the divided branch of the popliteal was ligatured. On removal of compression from the common femoral no blood flowed, and it was evident that the obstruction higher up had only been partially and temporarily displaced. Had the patient's condition allowed the surgeon should have attempted to pass long crocodile forceps up to the bifurcation of the aorta, to seize the clot, and to drag it out, a proceeding which is certainly practicable. Under the circumstances, the divided ends of the profunda were tied off, and the skin incisions sutured. The patient died twenty-four hours later in a typhoid condition, with commencing gangrene of the limb. At the necropsy, the left auricle contained a shred of ante-mortem clot in one of its recesses. The orifice of the left common iliac artery was blocked by a decolorized and adherent mass of clot which exhibited transverse markings apparently corresponding to the musculi pectinati of the auricular appendix. The clot projected some little distance into the abdominal aorta. Below it the arteries were filled by soft, non adherent clot. The rest of the post mortem appearances need not be detailed. The herniated intestine had retained its vitality, but the lower part of the large intestine was intensely congested and its vessels were filled by ante-mortem thrombus. Evidently one or more emboli had lodged in the arteries of this portion of the gut.

A Case of Cerebellar Hemorrhage.—The patient of H. M. Ingalis and P. C. Fenwick was a woman of twenty-two years admitted to hospital in a semi conscious condition. She had had a recent numbness over the left lower face, slight headaches, and occasional giddiness. She improved, but a few days later became semi-conscious and was sent to hospital. Speech was then unintelligible. She swallowed slowly, had no fever, aural discharge, was not deaf, could protrude her tongue, and had normal pupils. The right patellar reflex was exaggerated, the left normal. There was no ankle clonus and no rigidity of the head. The left arm and leg were partially paralyzed, but there were no twitchings or convulsions. Urine was normal. Three days later, slight left ptosis was noted, the pupils became widely dilated, insensitive in the left, and sluggish in the right. Left arm could not be moved. A curious habit of shaking the bed as if in play came on. On the fifth day after admission she was in the same semi-conscious condition. Babinski's sign was well marked and everything was symmetrorous. The head and eyes were turned to the right. Three days later Cheyne-Stokes respiration, anuria, rising temperature, and rapid pulse were noted. She died eight days after admission. Autopsy showed that the surface of the brain was deeply congested, but that there were no adhesions between the pia and dura mater. The dura mater was adherent to the skull-cap. At the base of the skull the meninges were densely adherent, especially in the middle fossa. On removing the brain a small clear cyst, the size of a split pea, was seen lying at the posterior extremity of the pons on the right side, overlapped by the cerebellum. This had no apparent connection with any deeper structure, as it was removed at a touch. The brain was normal except for general congestion, but in the right side of the cerebellum a cavity about one inch in length, which would just admit the tip of the little finger, was found. This cavity was filled with old blood clot adherent to the walls of the cavity. The brain tissue over this area was extremely friable. No thrombosis or embolism was found, and we could not detect any disease of the vessels. The authors summarize some of the previously reported cases similar to their own.

Deutsche medizinische Wochenschrift, September 19, 1907.

The Use of Curare in Frog Experiments.—Jacobi says that as it is growing increasingly difficult to obtain reliable specimens of this drug, it is advisable to use economy in its employment. Inasmuch as solutions of the poison decompose quickly, and lose their efficacy comparatively soon, he proposes the following method of preservation. The solution is made and filtered, and is then poured on to a piece of filter ruled with a lead pencil into square centimeters. This piece of saturated paper is dried in vacuo over sulphuric acid, and is then cut into portions measuring one-half or one square centimeter each. If 25 mg. of the drug is used in the solution and 200 sq. cm. of paper is saturated, each sq. cm. will contain one-eighth mg. of curare. One square of this size placed in the abdominal lymph sac suffices to curarize completely a frog of medium size. The method enables accurate dosage without the necessity of preparing fresh solutions, and is economical of material since the thoroughly dried slips of paper keep as well as the crude curare.

The Treatment of Malignant Growths With Organ Extracts.—Bergell and Sticker speak of the results that have already been obtained in cases of experimental new growths by injecting substances extracted from normal livers. In this way it has been possible to produce necrosis and liquefaction of carcinomas and sarcomas, and the theory has been suggested that the unrestrained growth of malignant neoplasms is due to the absence or insufficient quantity of similar ferment like bodies. These results have not as yet been susceptible of clinical application, however, since it has so far not been found possible to produce the local effect without also giving rise to toxic symptoms. In experiments on mice it was also found impossible to cause complete disintegration of the tumor without endangering the life of the animal through the toxic action of the organ extracts. In the present communication the authors describe a similar effect which was produced on advanced experimental sarcoma of the dog. The injection of the specific liver ferments caused regressive changes in the growth leading to its complete disappearance after it had already reached a stage of development that excluded the possibility of spontaneous cure. In this instance also the authors warn against a too sanguine attitude in regard to the application of the method to similar conditions in man, though they consider that the results obtained will be found of great theoretical value.

Action of Morphine Upon the Genital Apparatus of the Woman.—Lutaud has found, in the course of several years of treatment of drug *habitués* that the effect of the morphine habit on women is to stop menstruation and to take away all sexual desire. Others give the same experiences with men. The author thinks that we may make use of these facts in the treatment of gynecological diseases in which there is metrorrhagia with benefit to the patient. Such conditions are menorrhagia without lesions, menorrhagia and metrorrhagia due to fibromata, and that due to the destruction of tissue by cancer. In the first class of cases there are women whose profuse menstruation menaces life and here morphine may save life, and yet the patient need not become a morphine *habitué* if the drug is withdrawn skillfully. In fibromata its use may serve to tide over a few years until the menopause changes put an end to the growth of the fibroid and atrophy takes place. In cases of uterine cancer it is the duty of the physician to make of his patient a morphine taker, since only thus can she be comfortable for the rest of her existence. The author has seen cases in which the use of morphine has not only made the patient comfortable for years, but has actually prolonged life. It retards vital exchanges, lessens secretions, and retards the evolution of the neoplasm, and life is longer.—*Journal de Médecine de Paris.*

Book Reviews.

THE DIAGNOSIS AND MODERN TREATMENT OF PULMONARY CONSUMPTION, with special reference to the early recognition and the permanent arrest of the disease. By ARTHUR LATHAM, M.A., M.D. Oxon., M.A. Cantab., F.R.C.P. Lond.; author of the prize essay on the erection of the King Edward VII. Sanatorium; physician and lecturer of medicine at St. George's Hospital; senior assistant physician at the Brompton Hospital for Consumption and Diseases of the Chest; advisory physician to the Throat Hospital, Golden Square; advisory physician to the York Road Lying-In Hospital. New York: William Wood & Company, 1907.

THE third edition of Dr. Latham's little book follows in general character and largely in text the former editions of this work. As the title page indicates, the work is confined to a treatise on the diagnosis and modern treatment of phthisis, and the author has refrained from any considerable discussion of the pathological aspects of the disease. In the present edition the author has added much of recent interest, especially touching the later developments in the therapeutic use of tuberculin and a somewhat too brief review of the subject of the opsonic index in its relation to the diagnosis and treatment of tuberculosis. The principles governing the open-air method of treatment as carried out in Sanatoria are quite fully discussed in chapter 5, while chapter 6 is devoted to a discussion of the same method applied to the home. In these chapters it is clear that the author has been very largely influenced by Walther of Nordrach Sanatorium, whose ideas, while undoubtedly sound for the most part, are far from being universally applicable. The appendix contains brief but very clear instructions for staining tubercle bacilli, for determining the opsonic index, and for disinfection by means of formaldehyde gas. The book is very readable and presents in a most interesting form much that is essential to the equipment of the modern general practitioner of medicine. Besides a very full index, marginal notes make the work particularly convenient for quick reference.

KITTY DIXON, BELLE OF THE SOUTH ANNA. A WEE BIT OF LOVE AND WAR. By C. A. BRYCE, M.D. A Jamestown Year Souvenir of "Old Virginia."

THIS is a charming little story, well written, and attractively bound in blue and gray. It will form a welcome addition to the literature of the waiting-room; and there is no one, physician or patient, who will not enjoy reading it and also be the better for so doing.

ELEMENTS OF HUMAN PHYSIOLOGY. By ERNEST H. STARLING, M.D., Lond., F.R.C.P., F.R.S., Jodrell Professor of Physiology, University College, London. Eighth Edition. Chicago: W. T. Keener & Co., 1907.

IN the present volume the author has endeavored to give in the smallest possible compass what he believes to be the essentials of physiology, such as every medical student should be more or less acquainted with. These absolute essentials fill over 700 pages; and as the histological references are but few the bulk of the book consists of physiology. The work is divided into eighteen chapters; one hundred pages are devoted to muscles and nerves, about the same number to the circulatory system, digestion and metabolism, and the brain and nervous system each take up another hundred pages. The book is written from the point of view of the professor and laboratory worker, and is characterized by accuracy of statement and clearness of diction. In spite of the title, the book is by no means elementary, although it will appeal to the student rather than to the practising physician.

A MANUAL OF PERSONAL HYGIENE: Proper Living Upon a Physiologic Basis. By American Authors. Edited by WALTER L. PYLE, M.D., Assistant Surgeon to the Wills Eye Hospital, Philadelphia. Third Revised Edition. Philadelphia and London: W. B. Saunders Company, 1907.

DR. PYLE'S very practical manual of hygiene was among the first of the works, whose name is now legion, dealing in a popular way with practical suggestions regarding the preservation of health by means of proper living. It is in a way a system (as the term is now understood) of popular hygiene, being written by a number of specialists. These are Drs. Charles G. Stockton, on the digestive apparatus; George Howard Fox, on the skin and its appendages; E. Fletcher Ingals, on the vocal and respiratory apparatus; B. Alexander Randall, on the ear; Walter L. Pyle, on the eye; J. W. Courtney, on the brain and nervous system; G. N. Stewart, on physical exercise, and D. H. Bergey, on domestic hygiene. To the medical man those names offer a guarantee that the subjects on which they write are treated of by men who know what they are writing about; and no one can therefore hesitate to recommend the book to his clients, who, if they follow the advice here given, will be apt to need his services less frequently. In the present edition there is an appendix dealing with the significance of pulse, temperature, and respiration, with directions for carrying out the simplest procedures of hydrotherapy, thermotherapy, and mechanotherapy and with first aid in medical and surgical accidents and emergencies. The book can be warmly commended to the laity as a safe guide to health, and one which does not transgress by trying to impart the little strictly medical knowledge which is such a dangerous thing.

DAS DEUTSCHE BAEDERBUCH, An Encyclopædia of German Balneology Compiled by the Most Eminent Scientists with the Cooperation of the Imperial German Board of Health. 648 pages in large 4to, with 13 colored plates showing the graphic comparison of spring water analyses, a general map, and Hellmann's rain map. Leipzig: J. J. Weber, 1907.

THIS is an official scientific guide to the German health resorts, comprising a full description of all the German medicinal springs, watering places, etc. It has been composed by a large number of balneological specialists with the aid of other authorities. The introduction forms a survey on the present state of German balneology (geology, chemistry, pharmacology, therapeutics, climatology, political economy, etc.). The analyses are computed not only in the older way, according to the actual quantities of the various salts, but also in the new way, according to the metallic (kation) and the acid (anion) equivalents. The places are arranged alphabetically in the body of the work, but there is an index in which the various resorts are grouped according to their nature, whether spas, seaside, or climatic resorts, and the spas according to the chemical composition of the waters; there is also an index according to the different States of the German Empire. The book is a mine of valuable information to all seeking knowledge of any of the German health resorts.

AMERICAN MEDICAL DIRECTORY. Volume I. A Register of Legally Qualified Physicians of the United States and Canada. Chicago: American Medical Association, 1906.

THIS book contains a general directory of the physicians of the United States and Canada, arranged by States and towns, a general alphabetical directory of physicians, with present address, a directory of medical officers of the United States Army, United States Navy, and United States Public Health and Marine Hospital Service; a list of United States Pension Examiners, and a directory of physicians engaged in special lines of practice. It also contains, under each State, the medical practice laws, a list of the members of the State Board of Health and of the Board of Medical Examiners, medical colleges in the State with information concerning each, principal hospitals, sanatoria, and health resorts, and the officers of State medical associations with roster of component county society officers. The work is dated 1906, but it was not issued until late in the spring of 1907, and the date of the copyright is 1907. The earlier date of the title page may be offered as an excuse for the fact that the information contained in the book is in many cases a year or more behind the time. For example, Dr. Joseph D. Bryant is said to be the president of the Medical Society of the State of New York, although he ceased to hold that office several months before the directory was issued. The editor of the work had the assistance of the secretaries of the State and county medical societies in preparing his list of legally qualified physicians, and the information in the directory is therefore presumably correct and absolutely reliable. Unfortunately it is not. We have looked for the names of a hundred physicians selected at random, and have found errors in the way of omissions and incorrect addresses in over ten per cent. This is a poor showing for an official directory. The New York City list is jumbled badly as regards the arrangements of the boroughs. One feature of the directory is what purports to be a list of members of special societies. This is absurdly incomplete and worse than useless. Membership in such purely local societies as the Kansas City Medical Club and the Philadelphia Academy of Surgery is noted, yet such important societies as the Association of American Physicians, the American Academy of Medicine, the American Climatological Association, the American Laryngological Association, and numbers of others are ignored.

Altogether, although the directory is useful in a way, it is incomplete and unreliable, and we are disappointed in its arrangement and in finding it so weak, where, with all its advantages of official information, it should have been strong if not perfect.

Society Reports.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS.

Held at the Academy of Medicine, New York City, September 9 to 14, 1907.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 584.*)

Thursday, September 12—Fourth Day.

DR. ANDREW R. ROBINSON OF NEW YORK AND PROF. E. GAUCHER OF PARIS, VICE-PRESIDENTS, IN THE CHAIR.

THE first two hours of the morning session were devoted to the exhibition of patients and formal discussion on the same.

Further Experience with the White Light and Blue Light of the Quartz Lamp.—Prof. E. KROMAYER of Berlin, Germany, in this paper presented the following conclusions: 1. Light treatment with the quartz lamp was simple, and might be conveniently carried out by any physician having electric connections at his disposal. 2. The white light of the quartz lamp surpassed all other sources of light employed in therapeutics up to the present day in ultraviolet rays. It was indicated in all those cases where the object was to produce a superficial inflammation, such as alopecia areata, eczema, acne, furuncle, lupus erythematosus, and ulcers. 3. The blue light of the quartz lamp surpassed the Finsen light in its deep action. It was indicated in lupus vulgaris, lupus erythematosus, cancroid, vascular nævi, telangiectases, acne rosacea, and ulcers.

The Specific Action of Radium as a Unique Force in Therapeutics.—By Dr. ROBERT ABBE of New York. (See page 589.)

Dr. JAY F. SCHAMBERG of Philadelphia said he could confirm Dr. Abbe's results in the treatment of cutaneous growths, particularly superficial epitheliomata, warts, and similar affections. The question arose, however, did radium do any more in these conditions than the *x*-ray? Unless it could be shown to be more efficient, there would be no advantage in preferring the use of radium to the *x*-ray. The advantages of radium lay in the simplicity of its application, and the fact that it could be used in inaccessible cavities where the *x*-ray could not be applied.

Dr. HERMAN LAWRENCE of Melbourne, Australia, said that in cases of rodent ulcer of the eyelid he regarded radium as the best method of treatment, particularly as it removed the lesion without leaving a scar. Also in seborrheal keratosis senilis, in which cases there was a great tendency to atrophy of the skin after the use of the *x*-ray. He had also used it to advantage in the treatment of pigmented moles, and in seborrheal eczema of the eyebrow.

The discussion was continued by Dr. H. Radcliffe-Crocker of London, and was closed by Dr. Abbe.

The Therapeutic Effect of Radium in Dermatology.—By Dr. L. WICKHAM of Paris, France.

The Effect of Roentgen Rays on Paget's Disease of the Breast.—By Dr. TERZAGLII and Prof. R. CAMPANA of Rome, Italy. The authors stated that some forms of eczema of the breast and nipple frequently were neglected and at times assumed a chronic and malignant form, as of epithelial tumor, a form which had been named from the author first describing it as "Paget's disease." The authors then reported in detail the history of a case that threatened to assume the above form of disease in which the affected tissues apparently resumed their normal condition under the application of the Roentgen rays. The method was repeated in another case, with the same favorable results. These two experiments, Prof. Campana said, did not seem to him to be without interest when we reflected on the extremely malignant course of Paget's disease.

Progress in Radiotherapeutics.—By Dr. H. STREBEL of Munich, Germany.

X-Ray Baths and Dermametropathism.—Dr. HERMAN LAWRENCE of Melbourne, Australia, termed the *x*-ray bath as one in which the *x*-ray was applied to the skin of the entire body at one time, and he described in detail its method of application. The speaker said he had treated some 500 cases of skin disease by radiotherapy, and he believed that he secured better results by the method of giving several mild exposures as compared with the method of giving a heavy dose and then waiting to see the result on the patient's skin. He had used the bath successfully in mycosis fungoides, generalized eczema, psoriasis, obstinate urticaria, and pruritus; also in children in very troublesome cases of lichen urticatus. Dermametropathism was a word he had coined; it was meant to express a system of measuring disease of the skin, and it was based upon the result produced upon the skin by pressure with a smooth instrument, such as a penhandle. The author contended that by this method of clinical observation, which he called "skin marking," certain markings indicated the chronicity of certain diseases, and in some cases in adults the near onset of a relapse; also, that it explained the exaggeration of symptoms in some cases.

A Report of the Results in a Series of Epitheliomata Treated with X-Rays More Than Three Years Ago.—Dr. WILLIAM ALLEN PUSEY of Chicago read this paper, in which he gave the following summary: Of the thirty-one cases which were classed as not entirely successful, twenty-eight were cases which had failed of relief under other forms of treatment; only three were primary cases. These three were included in the group of failures, and they were all carcinomata involving the orbit. They were inoperable and occurred in patients who had abandoned treatment before any result might have been expected. In this entire list of twenty-nine unsuccessful cases, there were only five in which, in the author's opinion, there was any hope of cure by other methods of treatment. All of these five cases had previously been treated surgically, and all had been referred to him by surgeons. One case in the practically successful group was an epithelioma involving the external auditory canal. The other four cases were among the failures; in three of these there had been good grounds for expecting successful results from operation, but the patients would neither submit to operation nor complete their *x*-ray treatment. Among the entire list of 111 cases treated there were only three failures in which there was any reasonable hope of success. Twenty-eight of the 111 cases were either hopeless or most unpromising so far as any other method of treatment was concerned; of the eighty-three remaining cases eighty were successful. Counting thirty-one cases as failures, there were eighty successful cases in a list of 111 successive cases of epithelioma treated more than three years ago, a showing of 72.5 per cent. of successful results in 111 unselected cases.

Report of 800 Dermatological Cases With X-Ray and High Frequency Currents at the Mount Sinai Hospital (Dr. Lustgarten's Clinic).—By Dr. SAMUEL STERN of New York. The author stated that the respective standing of radiotherapy in dermatology could only be established by continued experiments and by collecting statistics of results accomplished. The method in which the *x*-ray did its work was probably by cell destruction, which led to the degeneration of the elastic and connective tissues. In epithelioma the results accomplished depended upon the proper choice of cases. The most favorable were those situated on the surface of the epidermis. The best results were achieved by a combination of *x*-ray and high frequency spark. In deep-seated carcinoma there was very little to be expected. It was more encouraging in the various forms of sarcoma. In acne vulgaris the results were very gratifying, while in acne rosacea there was little to be accomplished. In psoriasis the value of the *x*-ray was

well established; also in different forms of eczema. Lichen chronicus, lichen planus, and lichenoid eczema were conditions that were more stubborn, but they generally yielded to *x*-ray treatment. Lupus erythematosus did well with the high frequency spark treatment, but it often recurred. Lupus vulgaris affecting the mucous membrane was best treated with the *x*-ray, and other parts of the skin with the high frequency spark. Various types of verrucæ and nævi could be readily destroyed with the high frequency spark. In keloid, to expect permanent results, we must persist with the *x*-ray until a fair degree of dermatitis was produced. Folliculitis decalvans yielded well to *x*-ray treatment. Pruritus was benefited by both the *x*-ray and the high frequency current. Mycosis fungoides could be indefinitely controlled by the *x*-ray, but not cured. Unless the treatment was kept up, the lesions returned. In rhinoscleroma we could probably get a definite cure. In sycosis, favus, and trichophytosis capitis the results accomplished with the *x*-ray were very satisfactory, but in the two latter conditions other treatment was necessary. Hypertrichosis could be cured with the *x*-ray, but this required very careful technique. Hyperidrosis might be benefited, but only after a long series of treatments.

Dr. Neuberger of Nuremberg, Germany, referred to a case of Paget's disease of the penis in which the effect of the *x*-ray treatment in the beginning was very marked, the affection apparently being cured. It subsequently recurred, however, and then the *x*-rays had seemingly lost their effect. The ureteral orifice became narrowed, so that micturition was impossible, and amputation finally became imperative.

Dr. M. B. Hartzell of Philadelphia said that while he was willing to admit that the proper treatment of epithelioma of the lower lip was excision, with removal of the adjacent glands, there were certain cases in which resort to the *x*-rays was entirely proper and sometimes necessary. In acne he believed the *x*-ray treatment should be reserved for the cases which failed to improve under other methods. We were beginning to learn that the application of the *x*-rays to the face was apt to be followed by distinct atrophy of the skin, which was very disfiguring.

Dr. Burnside Foster of St. Paul said he had seen deplorable results follow the *x*-ray treatment in cases of psoriasis, eczema, favus, and ringworm, and they were largely due to the method in which the treatment was applied by inexperienced operators.

Dr. Francis J. Shepherd of Montreal said that in certain cases of epithelioma, notably in lesions about the eyelids, the *x*-ray was probably the best method of treatment; but when it came to lesions of the lower lip and of the mucocutaneous surfaces the speaker said he would strongly object to the use of the rays, especially where there was early involvement of the glands. Under those conditions, surgical treatment was strongly indicated.

Dr. William A. Pusey of Chicago said he was willing to treat any epithelium with the *x*-rays in which a conservative surgeon did not consider it feasible or necessary to remove the contiguous glands. This at once eliminated all cases of epithelioma about the mucocutaneous junction where an operation was at all possible. It did not eliminate those in very old people, or those rare cases where an operation was not tolerated. Still, the *x*-ray should not be restricted to any particular field. If it was not as reliable in one case as in another, it was not worth while considering.

Prof. E. Gaucher of Paris, France, and Dr. Veiel of Cannstatt, Württemberg, both spoke in favor of conservatism in the use of the *x*-rays. The latter said he could recall many cases that were kept too long in the hands of the radiotherapists, and came too late to the surgeon.

Dr. Herman Lawrence of Melbourne, Australia, said he did not expect the *x*-ray baths described in his paper to be used by anyone who had not the proper experience with this agent. Otherwise the treatment might lead to even fatal results.

Dr. Samuel Stern of New York said that in dealing with deep-seated epitheliomata, or with old cases of keratosis where the skin was thick and hardened, it would take a long time to produce a reaction with the *x*-rays, and other methods of treatment were preferable.

AFTERNOON SESSION.

Dr. J. Nevins Hyde of Chicago, Prof. Robert Campana of Rome, Italy, and Dr. Samuel Sherwell of Brooklyn, Vice-Presidents, in the Chair.

Tropical Diseases of the Skin: The Relation of the Navy to the Study of Tropical Diseases.—By Dr. P. M. Rixey, Surgeon-General United States Navy, Washington, D. C. In this paper, which was read by Dr. G. E. H. Harmon, Medical Director, U. S. Navy, Dr. Rixey made the statement that, taking a period of ten years, he had found that diseases of the skin had practically caused twice as great damage to the health of the Navy as was caused by all other diseases of a quarantinable nature. When it was considered that he included such diseases as diphtheria, smallpox, scarlet fever, rötheln, etc., in this category, the basis for his statement could be appreciated. The actual proportion was as 1 to 1.8. Had he also included syphilitic affections of the skin, this disproportion would be greatly increased. Dr. Rixey said that when he was appointed Surgeon-General of the Navy in 1902, his first aim was to establish a school where the young officers of the Medical Corps of the Navy could be grounded in the essentials of medical research. Of the many tropical diseases due to animal parasites, and of the many which might hereafter be found to be of such etiology, it was his belief that for a proper appreciation of such conditions a sound working foundation in medical zoology was not only desirable, but essential. For honest and capable work in any branch of tropical medicine it was necessary that the worker be grounded not only in clinical observation, but he must possess a fair degree of proficiency in bacteriology, a good working knowledge of animal parasitology, and, besides, have enthusiasm for his work. The medical officers of the Navy were, while in tropical waters, constantly required to study or treat such affections as ringworm, and the peculiarly virulent manifestations of syphilis. Also such diseases as yaws, leprosy, ground itch, elephantiasis, tropical ulcer, and the like. The speaker also referred to gangosa, or rhinopharyngitis mutilans, which was studied by Daniels in the Fiji Islands, and was unfortunately very prevalent in the island of Guam. Those who had studied it most carefully were positive that it was not syphilis, and absolutely sure that it was not leprosy. Another puzzling affection was what was generally termed "climatic bubo." Here we had the picture of a prolonged, continued fever following more or less the increase or decrease of the glandular swellings.

Report on Tropical Diseases of the Skin.—By Dr. William Dubreuilh of Bordeaux, France. (Read by title.)

Tropical Diseases of the Skin.—Dr. H. Radcliffe-Crocker of London, England, exhibited a number of tables which showed that practically all exclusively tropical diseases of the skin were due to parasites of various kinds, and although there was still much room for further investigation, they also showed that much of our knowledge of their pathology had been worked out quite recently. Now that so many of those who were going to practice in the tropics were undergoing a course of training in modern pathological methods, we might well expect that in the near future still greater additions to our exact knowledge would be made. It was only exact knowledge which

would enable us, not perhaps to treat the diseases themselves better than we did now, but, still better, to adopt the most efficient means for the prevention and spread of affections of which the disabling effects and mortality were so great. How much could be done in this direction the results of the discovery of the relation of the mosquito to filaria, malaria, and yellow fever were known to all. The first of the tropical skin diseases mentioned by Dr. Crocker was tropical ringworm, which he said was probably universal in all tropical countries. Among other tropical skin affections discussed by the writer was erythrasma, which was due to the *Microsporon minutissimum* and developed in the form of patches in the groins and axillæ; these lesions were dull red in cold weather, while in hot weather they became bright red and itching, and extended to neighboring parts. He also referred to the vitiliginous squamous dermatosis which had been observed by Jeanselme on the coast of Annam and other parts of Indo-China; also to furunculosis orientalis and yaws, which he regarded as one of the most serious of tropical diseases on account of the severity of the lesions and of the enormous number of its victims in the countries in which it was endemic, which comprised, practically, the whole tropical zone. The main question was whether yaws and syphilis were identical or only analogous diseases. The clinical fact that the manifestations of yaws yielded to mercury and iodide of potassium, judiciously given, no doubt lent more color to the theory of identity, but it by no means proved it. He had met with one case of granuloma inguinale tropicum in a full-blooded negro, and with two cases of craw-craw from the west coast of Africa.

Some American Parasites of the Skin.—Dr. Charles Wardell Stiles of the United States Public Health and Marine Hospital Service, Washington, D. C., discussed the frequency of "ground itch" in the Southern States, in connection with uncinariasis, and gave a demonstration of preparations showing the larval hookworms passing through the skin. He also gave a presentation and description of specimens of a parasite new to the United States. This parasite was a branching, proliferating, bothriocephid, larval tapeworm, which occurred by hundreds in the subcutaneous connective tissue of man in Florida, and produced a swollen condition, with spots of acne-like appearance. The only similar case on record was published by Ijima (1905) of Tokio, Japan. The American parasite was very similar to and possibly identical with the Japanese form (*Sparganum proliferum*). He also gave a demonstration of original specimens of *Agamofilaria georgiana*, a thread worm recently described as a parasite in the kin of man in Georgia. Also, a demonstration of various stages in the life-history of some of the North American ticks (particularly *Dermacentor*) which attacked man.

The Clinical Groupings of Tropical Ulcers of the Philippines, with Some Negative Notes as to the Etiology and Treatment.—By Dr. E. R. Stitt of the United States Navy. The author stated that after observing in the natives many chronic ulcerations, which clinically did not differ from ulcerations which might be expected from badly infected and neglected wounds or from the infective granulomata, and that from a standpoint of history there was the single common note of long duration, the conclusion was arrived at that tropical ulcer, as described by the authorities, did not exist in the Philippines. Subsequently, the same thing was observed in Guam in studying an ulcerating disease known as gangosa. Among the natives affected with leprosy and gangosa there were a certain number called by the Spaniards the Llagosos, in whom there were frightful lesions of the lower extremity, possibly tuberculous, possibly tropical ulcer. Later on, among sailors at the Naval Hospital, Caracao, two distinct types of chronic ulcer were observed, the first conforming to Fayrer's description of Delhi boil, the second resembling Jeanselme's tropical phagedena. Smears from ulcers of the first type showed scarcely any polymorphonuclears; only cells of lymphocyte characteristics. There was nothing indicative of protozoa (Giemsa's stain). Smears from ulcerations of the second type showed the presence in abundance of a single organism, morphologically a corynebacterium. Polymorphonuclears were present in great profusion; no cocci. Among the methods of treatment reported negatively were mentioned the following: (a) artificial gastric juice; (b) excision of lesion; (c) cauterization with pure carbolic acid; (d) Bier's passive congestion; (e) massive doses of potassium iodide.

Gangosa, with Additional Notes.—By Drs. O. J. Mink and N. T. McLean, Passed Assistant Surgeons, U. S. Navy, Washington, D. C. The authors stated that since the publication of their original paper on this subject in 1906 additional literature, not available at Guam, had been studied, and a few further facts regarding certain phases of the disease had been obtained. The disease had existed in Guam for at least 150 years. Although only 125 cases had been examined at Guam, there were probably between 200 and 250 on the island, the population of which was about 11,000. The youngest ages at invasion were three and nine years; the oldest were fifty-four and fifty-nine years. In a series of 80 cases, 49 were in females and 31 in males. The natives of the various parts of the island were intimately associated by religious, marital, and commercial relations, but there was no evidence to show that heredity played any part in the transmission of the disease. The native theory, and that held by the Spaniards, gave food a prominent place in the causation of the disease. They believed that such foods as decomposed or very salty fish, especially if eaten raw, uncooked taro, and native pepper, were the direct causes of the disease. This theory seemed improbable. The disease had been considered a late manifestation of syphilis, but the authors stated that during eighteen months spent in Guam they did not see syphilis in any type among the native population, and they did not believe that it existed there. Their observations led them to believe that if there was a specific infecting agency the nature of it was yet undetermined. The majority of the cases occurred in pure blood natives. As the disease was not fatal, autopsy was possible only when death occurred from intercurrent disease. To those who had seen a case of gangosa, the diagnosis offered no difficulty. In a number of cases observed, the initial symptoms led to a diagnosis of tonsilitis, pharyngitis, and laryngitis of a mild degree. All showed a slight rise of temperature, and complained of soreness in the posterior nares and pharynx, with stiffness in the muscles of deglutition. The throat symptoms became localized, and on the third day a patch of yellowish gray membrane was observed on the soft palate in the first case, the uvula in the second, and on the right pillar in the third case. The membrane was elevated, thick and tenacious. On removal, the denuded surface bled freely. Within twenty-four hours of the appearance of the membrane the typical ulceration was established. On the area covered by the membrane a number of small depressions appeared. The ulcer which was formed had a punched-out appearance, with undermined edges, and a deep, uneven floor, covered with a yellowish-white, very offensive discharge. The depth of the ulcer rapidly increased, until, in the cases of the uvula and soft palate, the tissues were perforated by the seventh day. These cases were still under observation. Fulminating gangosa was differentiated from diphtheria by the absence of Klebs-Loeffler bacilli, and by the typical mutilation in those cases which survived. Excepting in the fulminating type, the disease, *per se*, was never fatal. The mutilations and complications were permanent, and caused corresponding disability. The treatment was essentially local and should aim to destroy the infected area.

Dr. W. F. Arnold, Lieutenant-Commander and Surgeon (retired), U. S. Navy, said that in order to correct a possible misapprehension that syphilis did not exist on the island of Guam he wished to state that during his short service there he saw a hospital attendant with distinct mucous patches, and subsequently he found the woman who had caused the infection. He also saw a Eurasian of some sort in one of the shops there who had syphilis. The speaker thought there was no doubt that syphilis could be introduced in the island, and that it would spread.

Notes on Chronic Ulcers of the Philippines.—By Dr. George C. Shattuck of Boston, Mass. (This paper was read by title.)

Filariasis.—By Dr. T. Tanaka of Tokio, Japan.

Demonstration of the Uses of Liquid Air in Dermatology.—By Dr. Charles T. Dade of New York.

Friday, September 13—Fifth Day.

Dr. Herman G. Klotz of New York, Dr. Robert W. Taylor of New York, and Prof. Wolff of Strasburg, Germany, Vice-Presidents, in the Chair.

Report on the Present Status of Our Knowledge of the Parasitology of Syphilis.—By Prof. Erich Hoffmann of Berlin, Germany. The author stated that the *Spirochæta pallida* had been demonstrated with great regularity in acquired syphilis, where it appeared in almost all the pathological products of the early stage, and frequently in late affections as well (papules, gummata, aortitis). It was sometimes found in the internal organs (spleen, suprarenal body, liver, lung, cerebral arteries) of patients who had died during the secondary stage. In the child or the fetus affected with congenital syphilis the internal organs in addition to the skin were often flooded with spirochetes, as it were. The *Spirochæta pallida* was best shown in smear preparations with Giemsa's solution, or in sections treated with silver; however, it was equally feasible to employ Giemsa's solution in tissue sections, and silver impregnation in smear preparations. Besides the rapid staining of Giemsa's method, the direct examination of fresh specimens under the darkened-field-illumination was most advisable for diagnostic purposes. The *Spirochæta pallida* had a predilection for the connective tissue, the lymph vessels, the walls of blood-vessels and the interepithelial interstices, but it was sometimes met with in the interior of certain cells; for instance, the hepatic and suprarenal cells, and leucocytes (phagocytosis). Its manner of distribution in the pathological products was often irregular. It found no favorable conditions for its existence in the circulating blood, probably because it was anaërobic. The fact that it occurred not infrequently in unchanged tissues was accounted for by the reaction on the part of the organism being very slow to follow its entrance. The *Spirochæta pallida* was characterized by the delicacy and weak refractive power of the thread; great length in proportion to depth; abruptness and regularity of the convolutions; common occurrence of long terminal threads. Thus as a rule it could be readily destinguished from other forms. Its multiplication, according to certain authors whose views Dr. Hoffman accepted, took place by longitudinal division, as in the trypanosomes. Others assumed transverse division, as in bacteria. A regular cycle of evolution and resting forms had not as yet been demonstrated. All culture experiments had failed, and only their increase in tissue segments seemed to have been successful. The *Spirochæta pallida* was undoubtedly the producer of syphilis, and was possessed of the same importance for the diagnosis of this disease as was the tubercle bacillus for the recognition of tuberculosis.

Dr. A. Buschke of Berlin, Germany, sent a paper which was read by title.

Dr. Oscar T. Schultz of Cleveland, O., read a paper on the same subject in which he stated that at the present time only *Cytoryctes luis* and *Spirochæta pallida* needed to be considered in a discussion of the parasitology of syphilis. The weight of evidence was against *Cytoryctes luis*, firstly as to its being a protozoon, and secondly as to its having anything to do with syphilis. The chief factors in favor of an etiological relationship between *Spirochæta pallida* and syphilis might be briefly summarized as follows: 1. *Spirochæta pallida* had characteristics sufficiently marked to permit the experienced observer to distinguish between it and other spiral organisms. 2. The organism was present in all the various manifestations of the disease. 3. It was found only in syphilis; not in any other condition. 4. It bore a definite relationship to those histopathological changes which were considered characteristic of syphilis. 5. After the use of mercury the amelioration of the cutaneous lesions and the disappearance of the spirochetes went fairly well hand in hand. 6. In the lesions of experimental syphilis in lower animals *Spirochæta pallida* was present and had the same characteristics as in the human disease. The protozoan nature of the parasite appeared more than probable. While the majority of cases of syphilis were easily recognized by the experienced dermatologist, the finding of *Spirochæta pallida* in a doubtful case was of the greatest value, and must be considered conclusive proof of the syphilitic nature of the case. Because it had thus far been impossible to obtain and grow the organism in pure culture, Koch's laws were not susceptible of proof. However, the constant presence of the parasite in the lesions of syphilis, its presence only in syphilis and not in other diseases, its definite relationship to the pathological changes, its morphological characteristics and its presence in the lesions of experimental syphilis in the lower animals furnished sufficient evidence to establish the etiological relationship of the *Spirochæta pallida* to syphilis.

Observations in Regard to the Spirochæta Pallida.—By Dr. Albert Dryer of Cologne, Germany.

Systematized Localizations of the Treponema Pallidum.—Dr. H. Hallopeau and Dr. Gastou of Paris, France. The authors stated that instead of being irregularly scattered without any apparent plan, syphilomata were often found to affect certain organs or certain regions exclusively. These systematized localizations were referable solely to those of the *Spirochæta* or *Treponema*. They might be divided into nine groups: 1. Organic systematizations. 2. Symmetrical systematizations. 3. Systematizations localized in areas of nerve distribution. 4. Systematizations by autoinoculation, either intra- or extra. 5. Systematizations dependent upon prior localizations of some other infectious disease. 6. Systematizations in congenital syphilis. 7. Systematizations through culture medium of microbic origin: (a) through microbes of indifferent character; (b) through association of the treponema with other specific microbes. 8. Systematizations through recurrent toxic irritation. 9. Systematizations through lack of elimination and treatment.

Dr. Ch. Wardell Stiles of Washington, D. C., said he thought too much stress had been laid upon the question of whether this organism reproduced by longitudinal or transverse division in its bearing upon the character of the organism itself. If it is reproduced by longitudinal division, the probabilities were in favor of the organism being a protozoon, but even if its mode of reproduction was by transverse division it might be either a protozoon or a bacterium.

Dr. Bolesaw Lapowski of New York said that while he did not wish to make the assertion that the *Spirochæta pallida* was not the causative factor of syphilis, he did

not believe that all the conclusions to that effect drawn by the readers of the papers were justified by the facts; in other words, that they had not proven their point, and that further investigations were necessary.

Thed iscussion was continued by Prof. Alex Renault of Paris, Dr. T. Tanaka of Tokio, Japan, and was closed by Prof. Hoffman.

The Dangers of Syphilitic Infection in Massage.—By Dr. Robert W. Taylor of New York. (See page 601.)

A Contribution to Heredo-Syphilology.—Dr. Robert W. Taylor of New York said it was evident that our early concepts concerning hereditary syphilis were largely erroneous and inadequate, and that the following summary of conclusions was warranted by up-to-date observations, studies, and results: 1. The absence of very early manifestations in heredo-syphilis was no criterion that the infant was not infected. Spontaneous involution of the diathesis was most rare, and could never be asserted. It was not a haphazard accident. 2. In many cases the early exanthematic manifestations might be wanting, but later on specific or dystrophic lesions might show themselves. 3. Treatment of the infected infant should always be promptly begun and persisted in as sedulously as in the adult acquired disease. 4. Age and treatment tended to cure the child. 5. The view that inherited syphilis was at first superficial and later became deep and visceral was false, since the whole organism was involved from very early life. 6. Syphilis hereditaria tarda was not exceptional. It might occur at about the eighth and twelfth years, and even earlier, and frequently was encountered at all periods up to the thirtieth year of life, and perhaps later.

Afternoon Session.

Dr. Veiel of Württemberg, Germany, and Dr. Abner Post of Boston, Mass., Vice-Presidents, in the Chair.

Quaternary or Attenuated Hereditary Syphilis of Reticular Tissues (Appendicitis, Adenoid Vegetations and Scrofula).—By Prof. E. Gaucher of Paris, France. According to the author, appendicitis might be the result of a syphilitic heredity in the second generation. His designation of the quatenary syphilis in acquired as well as hereditary cases corresponded to the parasyphilis of Fournier. This syphilitic or congenitally specific origin of appendicitis, which had been maintained by him since 1904, had given rise to a good deal of contradiction and was far from being generally conceded. The paucity, or rather the absence of accurate statistics, was referred by him to the fact that about 50 per cent. of all trained observers, namely, physicians, were themselves affected with syphilis. In the history of his appendicitis cases, the author almost invariably found syphilis, either acquired or congenital. Accurately speaking, among 32 cases of appendicitis there were 8 old syphilitics and 21 children of syphilitic parents. A very striking feature in the history of appendicitis was its frequent occurrence as a family disease. Instead of holding the grippe responsible, as was commonly done, this family appendicitis should be laid to the score of syphilis rather than any other cause of an infectious character. Syphilis, congenital or acquired, did not give rise to appendicitis directly; it was merely a predisposing factor, favoring the hypertrophy and chronic inflammation of the reticular tissue of the appendix, which thus became a suitable soil for the action of irritative, infectious or suppurative agents of all kinds. In other words, while appendicitis might possibly occur in the absence of syphilis, the lesion of the reticular tissue, which in the majority of cases constituted the preliminary or presuppurative stage of appendicitis, was almost invariably a manifestation of quaternary or attenuated syphilis. Specific heredity, either direct or in the second generation, was also the cause of hypertrophy of the reticular tissue of the antrum, terminating in the formation of adenoids. Congenital syphilis was found by the author in the majority of the children coming under observation for adenoid vegetations. In those cases where syphilis was not found in the parents, there was reason to suspect it in the grandparents, as in appendicitis. There was an interesting observation on record by Van Huysen showing the existence of appendicitis, adenoids, and convergent strabismus in the same heredosyphilitic children of the second generation. If it were more often sought for and more readily recognized, this specific heredity in the second generation would certainly furnish the etiological explanation of many a case of adenoids or appendicitis which was not at present referred to the true cause for lack of sufficient information. The recognition of the heredito-specific origin of adenoids was so much the more important, as the anatomical basis of scrofula must be referred to the existence of the vegetations, and the resulting suppuration of the antrum. Scrofula was a chronic intoxication of microbic origin, with its starting point in the antrum. The microbic toxins formed by the local suppuration were absorbed by the mucosa of the rhinopharynx, taken up by the lymphatics, and distributed by the circulation throughout the organism. Scrofula thus being derived from the chronic inflammation of the rhinopharynx, and the causative adenoids being of more or less remote syphilitic origin, it followed that scrofula was a sequel to quaternary hereditary syphilis. In other words, the primary and essential condition of scrofula consisted in hereditary syphilization. Disease of the cervical lymph glands, so commonly observed in these cases, did not invariably develop upon the soil of tuberculosis, but was sometimes dependent upon congenital syphilis.

Dr. Frederick R. Sturgis of New York said that while the remote effects of syphilis, directly transmitted, were frequently observed, he frankly confessed his disbelief in the theory of Prof. Gaucher that appendicitis, in the majority of cases, should be looked upon as a parasyphilitic manifestation. There were probably few persons who could not claim the honor of having had a syphilitic ancestor, and it was very doubtful that the effects of the disease were carried to the fourth generation, nor was he willing to concede the fact that because certain persons had been unfortunate enough to contract syphilis, therefore they would be syphilitic for all time.

Prof. Gaucher's paper was further discussed by Dr. DeKeyser of Brussels.

Syphilis in the Rabbit, Produced by Pure Cultures of the Syphilis Bacillus.—By Dr. Max von Niessen of Wiesbaden, Germany. (Read by title.)

The Pathology of Tropical Ulcer (Delhi Sore) and Mycetoma (Madura Foot).—By Dr. James Homer Wright of Boston, Mass. (Read by title.)

Endarteritis of the Peripheral Blood-Vessels of the Skin. A New Arterial Symptom of Syphilis and Its Relation to Cutis Marmorata, to Large Syphiloderma Maculosum, and to the Spirocheta.—By Prof. S. Ehrmann of Vienna, Austria. (Read by title.)

The Osteopathies of Hereditary-Quaternary Syphilis.—By Prof. E. Gaucher and Dr. A. Levy-Bing of Paris, France.

Radiograms of Syphilis of the Long Bones.—By Dr. Martin W. Ware of New York. The author stated that syphilitic affections of the bones had been the last of the bone diseases to be subjected to x-ray examinations. Whereas, it could not be claimed that a pathognomonic picture might be obtained in every instance, yet a succession of these radiograms showed a uniformity in the type of the findings which corresponded in a striking manner with the picture of the gross pathological appearances of syphilis of the bones. It was therefore justifiable to speak of "characteristic findings" in syphilis of the bones.

which, taken in conjunction with the data of the anamnesis, materially added to the certainty of the diagnosis. Furthermore, a prognosis might be based on the findings and the efficacy of treatment estimated by the regressive changes of the bones visible in the radiograms. Most characteristic was the periosteal involvement in syphilis of the bones, and the differentiation of syphilitic dactylitis from tuberculous dactylitis was very marked. Osteomyelitis of a chronic nature dependent on pus organisms might at times give *x*-ray pictures which were difficult to differentiate from those of syphilitic origin; the latter, however, were singled out by facts in the history of the case. On the whole, the productive character of the syphilitic inflammation of the bone manifested itself in the dense shadows of the radiogram. Gummatous deposits which caused absorption were discernible by the lighter shadows, but most commonly surrounded by the denser shadows of areas of bone consolidation. The atrophy of bone peculiar to tuberculosis was wanting in the radiograms of syphilitic bone disease.

Hutchinsonian Teeth; Their Variation and Their Value.—Dr. ABNER POST of Boston, Mass., in his paper, said that in order to appreciate the full value of Hutchinsonian teeth one must know their life history and their relation to other symptoms. They were formed before birth. They were often associated with keratitis and deafness (Hutchinsonian triad). The typical Hutchinsonian teeth were peg-shaped, notched, beveled from front to back, and often assumed an unnatural position toward each other. Many teeth were found which presented some but not all of these characteristics. These imperfect Hutchinsonian teeth were of value, when alone, in awakening suspicions; when connected with the other symptoms, in confirming a diagnosis of syphilis.

Peripheral Syphilitic Arteritis.—Dr. HERMANN G. KLOTZ of New York said that since the publication of Huebner in 1874 it had been known and generally accepted that syphilis might directly cause pathological processes in the arteries of the brain. It would seem obvious that arteries in other parts of the body might become similarly affected. A number of observations, showing arteritis of peripheral arteries due to syphilis had been published, but generally not much attention had been paid to them. Quite a number of such cases had been classed as Raynaud's disease, and syphilis was usually mentioned as one of the causes of that disease. What were really the essential features of Raynaud's disease? Could they be directly caused by syphilis? The writer then discussed the symptoms of peripheral syphilitic arteritis, and referred to his former publications on the subject. He emphasized the practical importance of distinguishing the cases of syphilitic arteritis from those of Raynaud's disease and of calling them by their proper name.

Dr. G. HOWARD FOX of New York said he felt convinced that the symptoms of Raynaud's disease, including local asphyxia and gangrene, could be caused by syphilis. Many cases of peripheral syphilitic endarteritis probably had gone unrecognized, and had been wrongly called Raynaud's disease. The true character of these cases should be recognized and proper treatment instituted.

Dr. A. RAVOGLI of Cincinnati said he considered Raynaud's disease and gangrene due to syphilitic endarteritis as two entirely distinct affections. He did not believe that Raynaud's disease was even a parasyphilitic affection. This disease remained unaffected by the use of mercury and potassium iodide, whereas in the gangrene of syphilitic endarteritis the antisyphilitic injections gave brilliant results.

A Simple and Rapid Micro-Chemical Method for the Detection of Mercury in the Urine.—By Dr. C. LOMBARDO of Modena, Italy.

Treatment of Syphilis.—By Dr. GEORGE K. SWINBURNE of New York. This was a plea for the avoidance of giving mercury in any form by the mouth, at least as the main reliance in the treatment of syphilis.

Clinical Reports on (*a*) Syphilitic Reinfection; (*b*) Syphilis Insontium.—By Dr. GEORGE K. SWINBURNE of New York. This paper gave the reports of three cases of chancre of the tonsil.

The Use of Mineral Waters in the Treatment of Syphilis.—By Dr. JEAN DARDEL of Aix-les-Bains, France. The author stated that the specific treatment of syphilis was, of course, mercury and the iodides, but very often physical and hygienic agents, such as the old treatment with mineral waters, etc., were needed in addition. These auxiliary agents had a complex end in view. They tended to strengthen the organism and aid it in its fight against the disease. They also increased the absorption of the mercury and its assimilation, so that an intensive or rapid effect could be obtained. There were three kinds of mineral waters that were useful in the treatment of syphilis —the sulphur, the common salt or muriated, and the arsenical waters. The therapeutic indications for each of these waters depended upon the condition of the patient and the state of the disease at the time.

The Treatment of Syphilis by the Products of the Brazilian Flora.—By Prof. EGAS MONIZ BARRETO DE ARAGAO of Bahia, Brazil.

Verrucæ Plantares; Their Prevalence in Boys and Young Men, and Their Pathology.—By Dr. JOHN T. BOWEN of Boston, Mass.

Saturday, September 14—Sixth Day.

DR. HENRY W. STELWAGON OF PHILADELPHIA IN THE CHAIR.

Zoster Arsenicalis.—By Dr. JOSEPH ZEISLER of Chicago, Ill. In this paper the author submitted brief notes of his own observations of eleven cases of arsenical zoster recorded in a period of twelve years. The main point in all of these cases was that arsenic was the chief internal medication, and in all of them there developed, after a variable period and usually when a maximum dosage had been reached, a clinically unmistakable zoster. In these eleven cases the underlying original trouble was psoriasis in five, lichen planus in three, pseudo-leukemia, alopecia areata, and erythema, each one case. The time interval required for the development of zoster varied from four and a half weeks as the shortest period to three months as the longest. It always occurred while the patient was still taking his arsenic, and usually when a high dosage had been reached. It seemed to the writer that the direct connection between the medication and the subsequent eruption of zoster in all these cases was easily established. To consider the appearance of zoster in all of them as a casual occurrence would mean to wilfully ignore the chronological development of clinical phenomena.

Dr. M. B. HARTZELL of Philadelphia said that considering the large number of cases in which arsenic was administered the occurrence of zoster arsenicalis must be regarded as comparatively rare. It seemed to depend not so much on the dose as the length of time during which the drug was administered.

Dr. JOSEPH GRINDON of St. Louis, in discussing the question raised by the reader of the paper whether the vesicular eruption following the use of arsenic was a true zoster or a medicinal rash, as Lewin would have it, said that in order to decide that point we must first agree as to what true zoster was. Clinically arsenical zoster was much the same as true zoster, but if one chose to limit that term to the zymotic disease, as taught by Erb, then arsenical zoster was not true zoster.

Dr. J. NEVINS HYDE of Chicago referred to the rarity of symmetrical zoster. He recently saw a case which was believed to be of that type, but which proved to be one of true zoster on the right side of the body, and arsenical dermatitis on the left.

The discussion was continued by Dr. [illegible] of Zwicau, Germany, Dr. C. F. Jappe of Davenport, Ia.; Prof. Erich Hoffmann of Berlin, Germany, and was closed by Dr. Zeisler.

Failure in Proteid Metabolism and Its Relation to the Production of Certain Types of Dermatitis. Dr. James C. Johnston and Dr. Hans J. Schwartz of New York read a paper on this subject. The cases in which urinary examinations were made included urticaria, erythema multiforme, eczema, psoriasis, dermatitis herpetiformis, prurigo, rosacea, and pruritis. The amount and percentage of the nitrogen bodies were determined, together with any abnormality that might appear, such as the presence of acetone and increase of indican. A definite relationship was often observed between disturbance of the normal ratios and outbreaks in the skin. In subacute and chronic cases there seemed to be a pathological level in the percentages indistinguishable from the normal slight variations. In cases of indigestion, gastric or intestinal, great changes in the nitrogen partition were rarely found. On the other hand, patients might have acute dermatitis of one sort or another with high rest percentage and low urea, and no perceptible indigestion. The conclusion seemed justified that the fault lay chiefly in the intermediary metabolism, a view possibly supported by the effect of thyroid treatment. There was no discernible effect of the toxemia on the kidney structure. Since the changes in the partition resulted chiefly from failure of urea synthesis, and as the members of the series were nontoxic in any ordinary dosage, probably the variations were to be viewed as results of the toxemia, like the lymphocytosis of squamous disease and the eosinophilia of bullous. The autointoxication itself seemed a result, not a cause of disturbed metabolism. Indicanuria indicated an accidental accession to the toxemia which had no relationship to disturbance in the nitrogen partition.

This paper was discussed by Dr. Martin F. Engman of St. Louis, Dr. Thomas C. Gilchrist of Baltimore, Prof. E. Gaucher of Paris, France, and the discussion was closed by Dr. Johnston.

Some Experimental Observations on Urticaria Factitia.—By Dr. T. Caspar Gilchrist of Baltimore, Md. This consisted of a lantern slide demonstration of the changes observed in the skin in urticaria factitia.

Dr. Gilchrist's paper was discussed by Dr. Herman Lawrence of Melbourne, Australia, and Dr. [illegible] of Zwicau, Germany.

A Case of Sarcoid.—Dr. S. Pollitzer of New York reported the case of a married woman, 35 years old, with tuberculosis pulmonum and a large cavity in the right lung, but well nourished and healthy looking. Her cutaneous affection began about five years ago with the sudden appearance of bright and dull red, round, or oval slightly elevated areas from five to twenty mm. in diameter, flat, with a perfectly normal surface and sharply defined border, without subjective sensation. When the patient was first seen two and a half years ago the lesions then present had not changed noticeably since their first appearance. They were located on the forehead, cheeks, neck, the shoulders, arms, and forearms, and one near the umbilicus; in all about fifteen lesions, which had appeared in succession at varying intervals. Two years later the patient was seen again. All the old lesions persisted almost unchanged; a few seemed less infiltrated and less red; no atrophy, no scarring. But in the meanwhile new lesions had appeared; a group of five on the tip and sides of the nose, one on each forearm, and one on the right leg above the angle. The latter, which had appeared four months before, was excised. One half of the lesion, used for histological study, showed sharply defined areas of infiltration, made up of epithelioid and a few giant cells, strongly resembling tubercle; no tubercle bacilli. The other half of the lesion in fine suspension was injected intraperitoneally into three guinea pigs, which, killed after six weeks, showed no sign of tuberculosis.

At the completion of the scientific portion of the program, the Secretary General, Dr. John A. Fordyce of New York, made a supplementary report, which was accepted. He stated that letters had been received from Prof. Unna of Hamburg and others expressing regret at their inability to be present and wishing the Congress every success.

Upon motion of Dr. M. B. Hartzell of Philadelphia, a unanimous vote of thanks was extended to the New York Academy of Medicine for its generosity in giving the use of its building to the Congress.

Dr. Stafford Taylor of Liverpool, England, moved that a vote of thanks be extended to the Organization Committee and all the officers and members who had done so much to make this Congress a success. The motion was seconded by Prof. Bertarelli and Prof. E. Gaucher of Paris, France, and was unanimously carried.

The President, Dr. James C. White of Boston, in his valedictory remarks, stated that the members of the Congress might well claim that the interests of dermatology had been advanced by this meeting, and that their mutual respect and attachment had been enlarged and strengthened. Might all find in its spirit and accomplishment fresh inspiration for future labors and progress. He thanked the members for the kind consideration they had shown the President and for the happily expressed appreciation of their efforts, and then declared the sixth International Dermatological Congress dissolved.

Function of the Glomeruli of the Kidney in Diuresis.—Vittorio de Bonis has demonstrated that the glomerular epithelium is not a simple filter, but a semipermeable membrane through which may pass a large amount of water or isotonic solution, carrying with it substances that are selected by the kidney epithelium themselves from the blood plasma in contact with them. The author then made experiments as to what substances would pass in this way, making use of various diuretics that stimulate the renal epithelium. The ones used were chloride of sodium, sulphate of sodium, glucose, lactose, and urea. His conclusions are given thus: The glomeruli are permeable to chloride of sodium, sulphate of sodium, glucose, lactose, and urea, and the elimination of these substances is through a glomerular filtration, while the epithelia of the canaliculi have a part in the extraction of these substances. The diuresis produced by these substances is the result of action on the glomeruli principally; the glomeruli are the first parts of the organ to feel an increase of osmotic pressure of the blood and respond immediately to this stimulus.—*Giornale Internazionale delle Scienze Mediche.*

Metrorrhagia Myopathica.—Brooke M. Anspach presents the following conclusions: Metrorrhagia myopathica stands for a distinct class of cases, which have heretofore been variously and incorrectly grouped under apoplexia uteri, endometritis senilis, and preclimacteric bleeding. Metrorrhagia myopathica is a symptom immediately dependent upon an anatomical or a physiological lesion of the uterine muscle. No anatomical lesion has as yet been demonstrated, but it will probably be found in the elastic-tissue constituents of the vessel walls and the subserous and supravascular layers. The physiological lesion is most likely an insufficient contractile power of the uterus. It is possible that the condition is purely functional, and there is no anatomical change which can be recognized. In cases of metrorrhagia myopathica the uterus is enlarged and softened; the os is patulous. Metrorrhagia myopathica does not occur in nulliparous women, and therefore it must have some connection with the child-bearing process. The diagnosis of metrorrhagia myopathica is justified only when all other possible causes for uterine hemorrhage have been excluded. This cannot be too strongly urged, especially in reference to carcinoma. The terms apoplexia uteri, senile endometritis, and preclimacteric bleeding as applied to these cases are incorrect and unscientific. While curettement, atmokausis, and so on, have little effect in cases of metrorrhagia myopathica, palliative measures should always be tried before adopting hysterectomy. Obliteration of the endometrial cavity by means of destructive atmokausis is the alternative of hysterectomy in these cases. It is, however, harder to perform correctly and more dangerous than hysterectomy, which is the operation of choice.—*University of Pennsylvania Medical Bulletin.*

Surgical Suggestions.

Mercury by Hypodermic.—According to Hale White, when it is desirable to get a syphilitic patient under the influence of mercury quickly, as in syphilis of the nervous system, it can be done by the deep gluteal injection of one-eighth of a grain of perchloride of mercury dissolved in five minims of water. This may be done once a day. No trouble will result locally if the needle and syringe are clean.—*Clinical Review.*

The High Operation for Varicocele.—D. D. Lewis says that the high operation for varicocele has certain advantages. The operation is performed in a field which can be readily sterilized, thus reducing the dangers of infection, and the scar is removed from the irritating secretions about the scrotum. The operation is readily performed under local anesthesia and through a small transverse incision. The center of the incision of three-fourths to one inch in length corresponds to the external abdominal ring, and is slightly above it. The skin and the fascia are incised, and the structures composing the spermatic card are lifted up on a Kocher's director. The intercolumnar, cremasteric, and transversalis fasciæ are next incised parallel to the cord. This permits of the separation of the veins of the pampiniform plexus, from the vas deferens and its accompanying veins. The veins of the plexus are next ligated and resected, the extent of the resection depending upon the size of the varicocele. The veins accompanying the vas deferens are undistributed. The ligatures applied to the veins to be resected are left long and tied later. This elevates the testicle. The spermatic artery is sacrificed in this operation, but the artery accompanying the vas deferens provides for the nutrition of the testicle. The fascia is next sutured with fine catgut, and the skin with horsehair. A triangle bandage is applied to support the scrotum and testicle. It is advisable to keep these patients in bed from eight to ten days, until the organization of the thrombus is complete. Unfortunate accidents, such as pulmonary embolism, have resulted from early activity on the part of the patient.—*Surgery, Gynecology and Obstetrics.*

Black Eyes.—Harman says that it is wiser never to apply lead lotions to contused eyelids, as there is always danger of permanent staining of the cornea being caused through unrecognized abrasions. There is at hand in every household the material for an ideal pack—the netted dish-cloth. Take a clean specimen, cut off a portion about 4 inches by 6 inches, fold it once, soak in the lotion to be chosen and apply to the face. It is so limp it will fit the part accurately; it is so loose that it only holds the lotion on the face, and allows the most free evaporation, and therefore cooling. The double layer forms a thickness of nearly a quarter of an inch, and as the lotion is evaporated fresh cold lotion can be dropped upon the pack, and it will diffuse through the network without requiring any change of position or reversing. For a lotion nothing is better than a 5 per cent. spirit lotion, scented with eau-de-Cologne or lavender water if elegance be required. Weak spirit applied to the conjunctiva causes a stinging sensation, so it is well to put some vaselin between the eyelids before using such a lotion: the grease will fill the palpebral fissure, clog the lashes, and prevent the entrance of the fluid to the conjunctiva. So, also, if the skin about the eye be broken it can be protected from the spirit by the grease. Astringent lotions are of doubtful utility—they scarcely act through unbroken skin. Hamamelis is a favorite application; it is quite harmless. Arnica is often employed, but it is not always harmless; it occasionally produces severe skin irritation and symptoms not unlike erysipelas.—*Clinical Journal.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

SOUTH CAROLINA STATE BOARD OF MEDICAL EXAMINERS.

June 11, 12, and 13, 1907.

GENERAL ANATOMY.

1. How many bones of the cranium? Name them. How many bones of the face? Name them.
2. What are tendons? Aponeuroses? Fasciæ?
3. Name the superficial muscles of the abdomen. Name the deep muscles of the abdomen.
4. Where does the brachial artery commence and terminate? Name its branches.
5. Give the origin and distribution of the third cranial nerve. Is it a sensory or a motor nerve?

SURGICAL OR REGIONAL ANATOMY.

1. For purposes of spinal anesthesia, or tapping the dural sac for diagnostic purposes, where would you make your puncture, and why?
2. What arteries are in danger in the operation of "paracentesis thoracis," and how would you guard against this?
3. In gunshot wounds of the intestines or bladder, rupture of an abscess or any organ in the abdominal cavity, what position would you place your patient in, and why?
4. Give surface marking of femoral artery. Most favorable point for ligature? Why? Most effectual point of compression in operations on thigh? Why?
5. Give surface marking of common carotid artery. Most favorable point for ligature. Most effectual point of compression in an injury to the external carotid.
6. What is the chief function of the great omentum? In what position would you place your patient to remove the omentum from your field of operation?
7. How would you determine the portion of small intestines in your hand in operations on same?
8. In fracture of neck of femur, internal to the capsular ligament, what are the characteristic symptoms and their causes? In fracture just below trochanter, what are the symptoms and causes?
9. What cranial nerve is most frequently paralyzed? Name three causes from its origin to distribution and symptoms.
10. What arteries would you tie in pylorectomy?

PHYSIOLOGY.

1. Describe in detail the events that occur during a single cardiac cycle, and the theories of the cause of the heart beat.
2. What are the physical and chemical properties of muscular tissue? What changes take place during muscular action?
3. Classify foods. Define digestion and describe digestion in the stomach and intestines, and state substances absorbed in each.
4. What would be the effect of a transverse section of the anterior root of a spinal nerve? The posterior root? An efferent nerve? An afferent nerve?
5. Enumerate the special centers contained in the medulla, and state over what function or structure each presides.

HYGIENE.

1. Mention some of the diseases induced by industrial pursuits, and give the special cause in each disease, and how prevented.
2. What are the effects of too much shade around a dwelling house, and why?
3. What abnormal conditions of the eyes are most common in school children, and how caused?
4. What derangements are liable to result from improperly constructed desks and seats in schoolrooms?
5. What is "State Medicine?" Discuss its vital importance to promoting a successful nation.
6. What is trachoma, and how should it be handled when occurring in a school child?
7. Define ptomains, give sources of origin and describe their agency in inducing disease, and give the symptoms produced by them.
8. What are the common impurities of drinking water, and how may such impurities be removed?
9. Mention in order of merit the best means of fumigating by formaldehyde gas. How is the gas formed, and what is the necessary temperature of the room?
10. Mention the preventable epidemic diseases, and state how you would stop spread of each.

[Juniors answer all of Physiology questions and Nos.

1, 3, 7, 9, 10 of Hygiene. Seniors answer all of Hygiene questions.]

MATERIA MEDICA.

1. Give names of two vasodilators.
2. Give names of two vasoconstrictors.
3. GGive names of two hydragogue carthartics.
4. Give names of two cholagogue carthartics.
5. Give dose and therapeutics of each.

THERAPEUTICS.

In treating the following diseases, give dose, frequency of administration, and physiological effect of drugs used; also other remedial measures used, giving the physiological effect and mode of use: 1. Typhoid fever. 2. Bronchitis. 3. Pneumonia. 4. Dysentery. 5. Cholera infantum. 6. Acute nephritis. 7. Acute rheumatism. 8. Acute neuritis. 9. Enterocolitis of infants.

10. Give symptoms of poisoning by lead, opium, strychnine, and arsenic. Also antidotal treatment for each.

CHEMISTRY AND MEDICAL PHYSICS.

1. Give chemical formula for argentic nitrate. How is it used in medicine?
2. Give chemical formula for sodium chloride, and state its chief function in the economy.
3. What is $CaSO_4$, and what property makes it useful in surgery?
4. What is the difference between the galvanic and faradic currents?
5. What instruments are used to measure electricity with?

PRACTICAL URANALYSIS, MICROSCOPY, AND TOXICOLOGY.

1. What is a urinometer, and what diseases does it help to diagnose?
2. What constituents help to render the urine acid?
3. Mention the essential parts of a microscope.
4. Give morphological difference between blood and pus corpuscles.
5. Mention some of the most frequent pathological constituents found in the urine under the microscope.
6. What does continuous low specific gravity indicate?
7. When may the specific gravity be below 1010 in health?
8. How are uric acid crystals deposited in test tubes? Give morphology.
9. Define toxicology.
10. Give symptoms of, and antidotes for, poisoning from cocaine, carbolic acid, and strychnine.

SURGERY.

1. What are general indications in treatment of wounds?
2. Erysipelas. (a) Definition. (b) Prognosis. (c) Treatment.
3. Inflammation. (a) Definition. (b) Varieties. (c) Causes. (d) Treatment.
4. Locate the fissure of Rolando.
5. Abscess of prostate gland. (a) Causes. (b) Symptoms. (c) Treatment.
6. Differential diagnosis and treatment between omental and complete inguinal hernia.
7. Give the several steps in the amputation of the ring finger at the junction of the metacarpophalangeal articulation.
8. Give symptoms and method of reducing backward dislocation of hip.
9. Man forty-five years of age found on street in coma, what is the matter with him, and what is your method of examination?
10. Give differential diagnosis between gumma and epithelioma

PRACTICE AND DISEASES OF CHILDREN

1. (a) Etiology, diagnosis, and treatment of cerebral hemorrhage. (b) Differentiate between locomotor ataxia and multiple neuritis.
2. Which of the valvular lesions of the heart is most likely to cause sudden death? Why? (b) What symptoms constitute the Adams-Stokes syndrome? What is the pathology?
3. Commence with the chill and give symptoms and signs of a lobar pneumonia in a man twenty five years old. Treatment you would use.
4. Give etiology, symptoms, and treatment of acute gastroduodenitis.
5. What are the causes of peritonitis?
6. (a) In the third week of typhoid fever, what complication may arise? (b) What measures would you use to reduce temperature in typhoid?
7. Make a diagnosis and give your reasons, from the following history and symptoms: A married women, age thirty-four, large and fat in person. She has had two children and three miscarriages, the last six weeks ago. Otherwise she says her health has always been good until within three or four months; has been in the habit of drinking beer freely. For two weeks there has been pronounced jaundice, anorexia, and bilious vomiting after eating; dizziness, flatulence, occasional diarrhea with pain in the epigastrium, slight edema of the feet and ankles. These symptoms have been increasing. There has been no headache, no hemorrhage, or chills. The tongue was clean, pulse 80, temperature 97.8°. The heart and lungs normal. The liver was much enlarged and smooth. The spleen was felt below the ribs. There was no ascites. Urine sp. gr. 1017, deep yellow color, and containing a trace of albumin and much bile. Sediment normal. Blood examination negative.
8. Pathology and symptoms of primary laryngeal diphtheria. How much antitoxin would you give at a dose, and how often would you repeat it?
9. Give the clinical history of a case of tuberculous meningitis.
10. Clinical evidences and treatment of rickets.

OBSTETRICS AND DISEASES OF WOMEN.

1. What is post-partum hemorrhage, and how would you treat it?
2. (a) What symptoms would cause you to fear the development of eclampsia? (b) What would you do to prevent it? (c) How would you treat it should it occur?
3. (a) What is septicemia? (b) What is sapremia? (c) How would you treat them?
4. (a) What would you do to prevent mastitis? (b) How would you treat it?
5. What are the objections to the use of ergot during labor?
6. What are the dangers to mother and child in a case of breech presentation?
7. What is meant by version, and what are the methods of performing it?
8. Give causes and treatment of dysmenorrhea.
9. (a) When and how would you repair a lacerated perineum? (b) What is the principal muscle torn in this condition?
10. Give treatment (palliative and curative) of a case of retroversion of the uterus.

BACTERIOLOGY AND PATHOLOGY.

1. (a) What is the most effective method of sterilization? (b) How would you sterilize culture media, and why?
2. Give serum test (Widal reaction) for typhoid fever.
3. Give method of staining cover-glass preparations.
4. Give condition of intestines in acute enterocolitis.
5. Give changes in liver in chronic alcoholism.

MEDICAL JURISPRUDENCE.

1. Give in detail method of examining a body before testifying as an expert at an inquest.
2. (a) Give difference in entrance and exit in gunshot wounds by (a) soft lead, (b) hard lead, or steel bullet.
3. How would you distinguish between an incised or punctured wound received before death and immediately after death?
4. Where death is due to violence, how would you tell whether it was an accident, a homicide, or a suicide? Give an example of each.
5. Where an abortion has been produced, how would you tell whether it was criminal or accidental?
6. Has a physician the right to destroy a new-born monster?
7. Explain the difference between expert and ordinary testimony.
8. Under what circumstances is a physician excused from obeying a subpœna?
9. How would you distinguish between feigned and real insanity?
10. Distinguish between iron rust and blood stain.

[Juniors will answer Nos. 1, 2, 3, 4, 7 questions on Medical Jurisprudence.]

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

SOUTH CAROLINA STATE BOARD OF MEDICAL EXAMINERS.

June 11, 12, *and* 13, 1907.

SURGICAL OR REGIONAL ANATOMY.

1. For spinal anesthesia the puncture may be made in any intervertebral space below the second lumbar vertebra; the space generally chosen is that between the third and fourth lumbar vertebræ, or the lumbosacral space. The

reason is to avoid injury to the spinal cord, which terminates at the level of the lower border of the first lumbar vertebra. In the child, the spinal cord terminates opposite the body of the third lumbar vertebra; hence in children the puncture should be made below the fourth lumbar vertebra.

2. The intercostals. By inserting the needle nearer the upper than the lower border of the ribs bounding the selected interspace.

3. In all operations in the pelvic and lower part of the abdominal cavities, the patient should be placed in the Trendelenburg position. This causes the intestines and viscera to be displaced away from the field of operation.

4. The surface marking of the femoral artery is a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle just above the internal condyle of the femur.

The most favorable point for ligature is at the apex of Scarpa's triangle, because here the vessel is more superficial, there are no large branches, and fewer important structures.

The most effectual point for compression in operations on the thigh is just below Poupart's ligament, because here the vessel is very superficial, and is separated only by the psoas muscle from the ascending ramus of the pubic bone; hence compression against that bone is easy and effectual.

5. The surface marking of the common carotid artery is a line drawn from the sternoclavicular articulation to the lobule of the ear, but the artery only extends as high up as the upper border of the thyroid cartilage.

The most favorable point for ligature is at the level of the cricoid cartilage in the superior carotid triangle, above the omohyoid muscle.

The most effectual point for compression is against the anterior tubercle of the transverse process of the sixth cervical vertebra (on a level with the cricoid cartilage).

6. The chief function of the great omentum is to afford protection to the small intestine.

In the Trendelenburg position.

7. "The jejunum is wider than the ileum (its diameter being a quarter of an inch greater than that of the ileum), and its coats are thicker and more vascular. If the gut be empty, and can be rendered translucent by being held against the light, the lines of the valvulæ conniventes can be well seen. These folds are large and numerous in the jejunum, but become small and scanty in the upper ileum, and are wanting in the lower third of that bowel." (Treves, *Surgical Applied Anatomy.*)

8. In intracapsular fracture: Swelling in front, just below Poupart's ligament, due to effusion of blood or to projection of the fragments. Shortening brought about by muscular contraction. Eversion or rotation outward, due to the weight of the limb, or the fact that the neck is often more extensively fractured behind, or it may be due to muscular action. In fracture below the trochanter the lower fragment is drawn up behind the upper one by the hamstrings, aided by the rectus, gracilis, sartorius, tensor vaginæ, and adductors, and is carried a little to its inner side under the influence of the last-named muscles. The lower end of the upper fragment usually projects forward and a little outward. This is produced by the agency of the lower fragment, which tilts the upper piece of bone in the direction named. In the fracture of the upper third of the shaft the projection forward of the upper fragment is aided by the ilio-psoas muscle." (Treves' *Surgical Applied Anatomy.*)

9. "The paralysis may depend either upon (1) central causes—*i.e.* blood-clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in *bulbar paralysis;* or (2) it may be paralyzed in its passage through the petrous bone by damage due to *middle-ear disease* or by *fractures of the base;* or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as *Bell's paralysis.* It may be due to exposure to cold or injury of the nerve either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the lower jaw." (Gray's *Anatomy.*)

10. The arteries to be tied in pylorectomy are: The gastric, the pyloric branch of the hepatic, the right and left gastroepiploics, the gastroduodenal.

PHYSIOLOGY.

2. The *physical properties* of muscular tissue are: Elasticity, cohesion, tonicity, irritability (to mechanical, chemical, electrical, or thermic stimuli), contractility, and conductivity.

The *chemical properties* include: Power of consuming oxygen and of excreting carbon dioxide and sarcolactic acid; acid reaction; the plasma can also coagulate.

During contraction the following changes take place in a muscle: (1) It becomes shorter and thicker, but (2) there is no change in volume; (3) there is an increased consumption of oxygen; (4) more carbon dioxide is set free; (5) sarcolactic acid is produced; and hence (6) the muscle becomes acid in reaction; (7) it becomes more extensible, and (8) less elastic; (9) there is an increase in heat production and consequently a rise of temperature; (10) the electrical reaction becomes relatively negative, and (11) a sound is produced.

3. Foods are classified as follows:

- I. Inorganic { Water. Salts.
- II. Organic { Non-nitrogenous { Carbohydrates. Fats. Nitrogenous—Proteids.

Digestion is the process by which the food is converted into material suitable for absorption and assimilation.

Substances that may be absorbed in the *stomach* are: Water, alcohol, salts, sugars, and dextrins that may have been converted from starch by the ptyalin of the saliva, and proteoses and peptones resulting from peptic digestion of proteids.

Substances that may be absorbed in the *intestines* are: Water, sugars, proteoses, peptones, and fats.

4. Transverse section of the *anterior root* of a spinal nerve causes loss of motion and degeneration of the peripheral portion of the anterior root fibers; the sensory fibers of the posterior root are not affected.

Transverse section of the *posterior root* of a spinal nerve causes loss of sensation and degeneration, which latter differs according as the section is made on the proximal or peripheral side of the ganglion. If the section is made between the cord and the ganglion, degeneration only occurs in the piece severed from the ganglion, but connected with the cord. If the section is made beyond the ganglion, degeneration occurs in the fibers peripheral to the lesion.

If an *efferent* nerve is severed, it will no longer convey impulses from the brain or cord.

If an *afferent* nerve is severed, it will no longer convey impulses to the brain or cord.

5. The special centers contained in the medulla are those for the following functions or actions: Respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

HYGIENE.

1. "Pulmonary phthisis: Accountants, bookkeepers, clerks, compositors, pressmen, marble and stone-cutters. Fibroid phthisis from dust: Grinders, file-cutters, potters, glass polishers, wool and cotton spinners, millers. Anthrax: Skin handlers. Internal anthrax: Wool and rag sorters. Glanders and tetanus: Hostlers. Anemia, gastric ulcer, eczema, erythema nodosum: Domestic servants (female). Varicose veins: Coachmen, shop girls, and others accustomed to long maintenance of the standing or part standing position. Writers' cramp (scriveners' palsy): Clerks and writers. Septic infection: Butchers and slaughter-house employees. Conjunctivitis: Electric light workers (probably caused by actinic rays). Nystagmus: Miners. Emphysema: Players upon wind instruments. Insomnia, dyspepsia, disease of liver and kidneys, neurasthenia, irritable heart, apoplexy, and paralysis: Brain workers. Typhoid fever, pneumonia, cardiovascular, and renal diseases, morphine and cocaine habits: Physicians. Lead poisoning: Lead miners and smelters, painters, gilders, makers of white and red lead, seamstresses (from silk thread loaded with acetate of lead), makers of artificial flowers. Mercurial poisoning: Cinnabar miners, makers of cheap looking-glasses or mirrors, and makers of felt hats. Arsenical poisoning: Wall-paper workers (formerly), workers on artificial flowers and fancy glazed-paper boxes. Phosphorus poisoning: Matchmakers. Chromium and zinc poisoning: "Founders' ague" in brass foundries. Disease of hair follicles: Operatives in oil refineries and paraffin works." (Butler's *Diagnostics of Internal Medicine.*)

2. Too much shade favors dampness, and the multiplication of molds and bacteria, which are readily conveyed into the house. Insects, mosquitos, etc., are also harbored. Further, absence of sunlight is an etiological factor of anemia and debility.

3. Myopia, hypermetropia, astigmatism, strabismus, and trachoma are the abnormal conditions of the eyes most common in school children.

4. Improperly constructed desks and seats are liable to cause spinal curvature, round shoulders, compression of the thorax, and defective vision.

5. "State medicine" comprises all those branches of

medical science which are concerned with public health, vital statistics, registration of diseases, quarantine, etc.

6. Trachoma is a contagious conjunctivitis, accompanied with granulations on the eyelids, and later on with cicatricial contraction or other deformity of the eyelids. Constant inspection and isolation of all cases are essential, in addition to the general treatment.

8. The common impurities of drinking water are: Calcium and magnesium salts, decayed animal or vegetable matter, sewage, disease germs, animalculæ, dust, and dirt. The best way to remove the impurities is by distilling or by boiling and filtering.

10. Probably all the epidemic diseases are preventable; certainly smallpox, typhoid, diphtheria, malaria, and yellow fever can be prevented. The spread of any epidemic can be prevented by proper isolation, quarantine, and hygiene; and by the use of special precautions such as vaccination (for smallpox), immunizing doses of antitoxin (in diphtheria), keeping out or destroying mosquitos (in malaria and yellow fever), etc.

MATERIA MEDICA.

1. Two vasodilators: Spirit of clonoin (nitroglycerin), dose ♏j; liquor ammonii acetatis, dose ʒiv.

2. Two vasoconstrictors: Ergot, dose of fluid extract, ♏xxx; adrenalin, dose of the chloride in solution of 1:1000, ♏v-x.

3. Two hydragogue cathartics: Croton oil, dose ♏j; elaterin, dose gr. 1/10.

4. Two cholagogue cathartics: Podophyllum, dose gr. x; massa hydrargyri, dose gr. j-x.

5. For doses, see questions 1 to 4 above.

THERAPEUTICS.

10. The *symptoms of acute lead poisoning* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms."

The antidotal treatment consists in administering "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube."

The *symptoms of poisoning by opium* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis, the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."

Treatment: "Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach, and in maintaining the respiration. In the first or second stage the 'ambulatory treatment' should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop, the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee, or caffein, by the mouth or rectum, are of benefit. The same cannot be said of atropin. The urine should be drawn by the catheter."

The *symptoms of poisoning by strychnine* are as follows: "Strychnine produces a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

Treatment: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible."

In *poisoning by arsenic*: *Symptoms*: "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities."

In *chronic cases*: "Inflammation of the conjunctivæ, with intolerance of light. Irritation of the skin, accompanied by an eruption (eczema arsenicale). Local paralyses. Great weakness and emaciation. Exfoliation of the cuticle and falling out of the hair."

The *antidote* is freshly prepared ferric hydroxide.—(From Witthaus' *Essentials of Chemistry*.)

CHEMISTRY AND MEDICAL PHYSICS.

1. The formula for argentic nitrate is: $AgNO_3$. It is used in medicine, *locally* as a stimulant, an astringent, a caustic, an escharotic, and an antiphlogistic. *Internally* it is used for ulcer and inflammation of the stomach and intestines; also in some forms of nervous diseases.

2. The chemical formula for sodium chloride is: NaCl. Its chief function in the economy is to aid in the process of osmosis, to aid in holding certain proteins in solution, and it is probably the source from which the hydrochloric acid of the stomach is derived.

3. $CaSo_4$ is calcium sulphate, called also plaster-of-Paris. It has the property of being able to take up water, when mixed with it, to form a hard and solid mass.

4. The galvanic current is constant and continuous; it always flows in the same direction; it has pronounced chemical and thermal effects.

The faradic current is a rapid succession of momentary impulses; the direction is not constant; the chemical and thermal effects are almost imperceptible.

5. The galvanometer, voltmeter, amperemeter, ohmmeter, coulombmeter, joulemeter, miliammeter.

PRACTICAL URANALYSIS, MICROSCOPY, AND TOXICOLOGY.

1. A urinometer is a form of hydrometer used for determining the specific gravity of the urine. It may be a help in the diagnosis of diabetes mellitus, diabetes insipidus, some diseases of the kidneys, chronic wasting diseases.

2. The acidity of the urine is chiefly due to the presence of acid sodium phosphate; also to some slight extent to uric acid and to carbonic acid.

3. The essential parts of a microscope are: The objective lenses, the eyepiece, the base, pillar, body, draw tube, coarse and fine adjustments, stage, mirror, diaphragm, condenser, and nosepiece.

4. Pus corpuscles are readily distinguished from blood corpuscles by being larger, distinctly granular, with an irregular outline.

5. Some of the most frequent pathological constituents found in the urine under the microscope are: Blood, pus cells, casts, cylindroids, epithelium, clap-threads, crystals, pathogenic bacteria, and foreign matter.

6. Continuous low specific gravity of the urine may indicate: Diabetes insipidus, chronic interstitial nephritis, or contracted kidney.

7. The specific gravity may be below 1010 in health:—when the person ingests a large quantity of fluid or voids more urine than normal.

8. Uric acid crystals may be deposited as a brick-dust sediment. They are found as rhombic plates with rounded edges, as tube shaped or pointed crystals, as lozenge shaped, and arranged in bundles or as crosses; they are generally more or less colored by the urinary pigments.

9. By *toxicology* is meant that branch of medical science which appertains to poisons; it includes their character, origin, actions, symptoms produced, antidotes, treatment, and detection.

10. In *cocaine poisoning* there will be found pain and fullness in the head, pulse first quick, later feeble and slow, extremities cold. The symptoms are not constant.

The *antidote* is said to be amyl nitrite.

Symptoms in carbolic acid poisoning: Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

The *antidote* is said to be alcohol.

For *strychnine poisoning*, see above, THERAPEUTICS, question 10.

SURGERY.

1. The general indications in the treatment of wounds are: To stop the bleeding, combat shock, remove foreign bodies and dead tissue, make aseptic, put the edges in apposition, drain (if necessary), dress, secure rest to the part, allay undue pain, and combat inflammation.

4. Draw a straight line over the top of the scalp from

the inion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of three and one-half inches. This line will represent the location of the fissure of Rolando.

6. An *omental hernia* is dull on percussion, does not yield a gurgle on manipulation, is firm and lobulated on palpation; whereas an *enterocele* is tympanitic on percussion, yields a gurgle on manipulation, and is smooth and elastic on palpation.

7. "The incision begins just above the head of the metacarpal, on its dorsal aspect—passes down the median dorsal aspect over the prominence of the knuckle, to just beyond the base of the first phalanx; at this point the hitherto median incision diverges into two symmetrical limbs—each sweeping across the dorso-lateral aspect of the finger to just below the junction of the finger with the web—and thence transversely across the palmar surface in the line of the crease, on a level with the free border of the web, coming to the opposite side just below the junction of the web with the finger. This rather extensive incision is best made with three strokes—from commencement to web of one side—from point of divergence of median line to web of opposite side—and across palmar surface connecting the two limbs. The above incision through skin and fascia is now deepened. The palmar portion is cut to the bone while the finger is forcibly extended. The lateral portions are carried to the bone, cutting the lumbricales and interossei. The soft parts are retracted to the joint line. The extensor tendons are then cut and the joint thus entered from the dorsum—the lateral ligaments and glenoid ligament being cut from within and the disarticulation completed. The two digital arteries are tied and the synovial sheath closed. The edges of the sides of the oval are sutured in one vertical, anteroposterior line, in continuation with the queue of the incision. The splint applied should include the wrist-joint." (Bickham's *Operative Surgery.*)

10.—

GUMMA.	EPITHELIOMA.
1. May occur in early or middle life.	1. Occurs late in life.
2. More rapid growth.	2. Slower growth.
3. History and signs of syphilis.	3. No such history or signs.
4. Follows secondary stage of syphilis.	4. Usually begins as a pimple or a wart.
5. Responds to mercury and potassium iodide.	5. Does not respond to medicines.
6. Not very painful.	6. Is attended by lancinating pain.
7. Ulceration generally multiple.	7. Ulceration single.
8. Edges not everted.	8. Edges everted and raised.
9. But little enlargement of lymph nodes.	9. Lymph nodes enlarged
10. Induration less marked.	10. Induration more pronounced.

PRACTICE AND DISEASES OF CHILDREN.

1. (*b*)

LOCOMOTOR ATAXIA	MULTIPLE NEURITIS.
1. Slow onset.	1. More rapid onset.
2. Lightning pains.	2. No lightning pains, but the muscles are tender to pressure.
3. Argyll-Robertson pupil.	3. No Argyll-Robertson pupil.
4. Girdle sensation.	4. No girdle sensation.
5. No actual loss of power.	5. Actual loss of power.
6. No paralysis or wasting of muscles.	6. Paralysis and wasting of muscles are present.

2. Aortic regurgitation is the valvular lesion of the heart most likely to cause sudden death. The suddenness of the death is due to paralysis of the left ventricle during diastole.

The *Adams-Stokes syndrome* is a pulse permanently slow, and accompanied by attacks of vertigo or syncope. It is supposed to be the "result of changes in the pneumogastric centers due to disease of the arteries of the medulla."

7. "Gallstone in the common duct is possible but unlikely, owing to the presence of splenic tumor, the lack of any intermission in the symptoms and the absence of pain, fever, or chills. Catarrhal jaundice cannot be excluded, though it rarely leads to much enlargement of the liver or spleen. The points against cancer are the [illegible] of pain, cachexia, or irregularities on the liver surface. Syphilis might produce all these symptoms and can be positively excluded only by the therapeutic test. *Cirrhosis, or the combination of cirrhosis and fatty infiltration, is the most likely diagnosis.* This accounts better than any other hypothesis for the splenic enlargement, the large, smooth liver, and the jaundice. The gastric symptoms would then result from passive congestion of the stomach." (Cabot's *Case Teaching in Medicine,* from which the question also is taken.)

8. In laryngeal diphtheria the dose of antitoxin is from 2,500 to 4,000 units, according to the age of the patient. The dose can be repeated in twelve hours if there is no marked improvement in the patient's condition.

OBSTETRICS AND DISEASES OF WOMEN.

5. The objections to the use of ergot during labor are: (1) That it may produce tetanic contractions of the uterus and so cause rupture of the uterus, death of the mother, or asphyxiation of the child; (2) that it increases the chances of lacerations of the cervix and perineum; (3) that it tends to cause retention of clots and membranes, etc.; and (4) that it retards the secretion of milk.

6. The dangers to mother and child in a case of breech presentation are: (1) Compression of the umbilical cord; (2) premature respiration; (3) asphyxiation of the child; (4) the child may suffer from fractures, dislocation, hemorrhage, or paralysis; (5) extension of the head, or of the arms over the head; (6) increased tendency to rupture of the perineum.

9. (*a*) The perineum should be repaired, if possible, immediately after labor, or within twenty-four hours.

(*b*) The principal muscle torn is the Transversus perinei.

10. The *palliative* treatment of retroversion of the uterus consists in: (1) Removing the cause, if possible; (2) replacing the uterus; (3) keeping the uterus in position by means of pessaries, tampons, and knee-chest position; (4) tampons, ichthyol, pelvic massage, and vaginal douches; (5) the enforcing of proper hygiene, particular attention being paid to the bowels, clothing, and exercise.

Curative treatment is operative, and the choice lies between ventral suspension of the uterus and shortening of the round ligament.

BACTERIOLOGY AND PATHOLOGY.

1. (*a*) The most effective method of sterilization is, for objects capable of withstanding it, *dry heat.*

(*b*) Culture media are best sterilized by streaming steam, because hot air sterilization would cause the water in the culture media to evaporate.

2. The Widal serum reaction "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

MEDICAL JURISPRUDENCE.

2. (*a*) In gunshot wounds by *soft lead bullets,* the *wound of entrance* is often smaller than the ball (skin stretched at the moment of impact and contracted after perforation); it is depressed, and the edges are contused and inverted, and if the weapon is fired within ten feet usually are blackened from powder and contain powder grains. If the wound is much larger than the bullet, it means that some foreign body has been carried in.

The *wound of exit* is everted, "triangular, linear, or stellate," and much larger than the wound of entrance.

(*b*) In gunshot wounds by *hard lead, or steel bullets,* the *wound of entrance* is usually as large as the ball, the skin may be split or may be perforated, and foreign bodies are not carried by the ball into the tissue.

The *wound of exit,* if not in the region of explosive action, may be a little larger or a little smaller than the bullet, but is not noticeably larger than the wound of entrance. If within the area of explosive action, the wound of exit is much larger than the wound of entrance, and is irregular and everted. (From Da Costa's *Modern Surgery.*)

3. It is impossible to distinguish between an incised or punctured wound received *before* death and *immediately after* death.

6. One has no right to destroy a new born monster.

7. In *expert* testimony, the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can only be done by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

In *ordinary* testimony, the witness testifies only to *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

8. A physician would probably be excused from obeying a subpœna under the following circumstances, accompanied by an affidavit in proper form: (1) If the physician himself were ill in bed; (2) if he were in actual attendance upon a patient, where his presence was absolutely requisite, and, he could not leave without endangering the patient; (3) if he were in attendance upon a very contagious case, such as smallpox or erysipelas, in which case his presence in court would be dangerous.

9. In *feigned insanity*: There is generally a very obvious motive for the claim of insanity; it is not urged until after the committal of some crime, or until there is some benefit to be derived from the plea of insanity; the person is generally very desirous of being considered insane, and urges his claims in this direction. It is often impossible to distinguish feigned from real insanity.

10. Some of the material from the suspected stain is thoroughly mixed with a few drops of a saturated solution of sodium chloride, and then allowed to evaporate to dryness on a slide covered with a cover-glass. Now add a drop of glacial acetic acid to the slide, and allow it to enter under the cover slip; then apply gentle warmth. If the suspected stain is *blood*, crystals of hemin will form later, and can be seen under the microscope; this will not be the case with *iron rust*.

BULLETIN OF APPROACHING EXAMINATIONS †

STATE	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H Sanders, Montgomery	Montgomery		
Arizona*	Ancil Martin, Phœnix	Phoenix	Jan	6

ON THE ASYMMETRY OF THE CYCLE OF LIFE, BEING "THE END OF THE THREAD."

By JOHN BEARD, D.Sc.,

EDINBURGH.

"I have, in fact, set up a theory of molecular asymmetry, one of the most important and wholly surprising chapters of science, which opens up a new, distant, but definite horizon for physiology." *Louis Pasteur* 1860).

"I regard as necessary the extension of Van't Hoff's theory, to tentavalent nitrogen, as a completely justified amplification of our chemical views."—*J. Wislicenus* 1877

With the opening of the winter semester of the University of Würzburg, about October 21, 1907, twenty-five years will have elapsed since the writer of these lines first entered the Research Institute of the late Professor Carl Semper. Nineteen years have passed since a certain thread of research was picked up, years of work, absorbing, entrancing, and arduous. As the hill was ascended slowly, new and ravishing prospects were ever revealing themselves, the view widened constantly, but the summit seemed unattainable. Indeed, hope had been abandoned of viewing from it the Promised Land.

"Ich steige schon dreihundert Jahr,
Und kann den Gipfel nicht erreichen.
Ich wäre gern bei meines Gleichen."
—Goethe's *Faust.*

Every new unraveling of the thread led to new problems. But no matter how many side branches or collateral issues came up, the main course of the thread was continuous, and the observer's senses were concentrated upon it to the exclusion of all else. Among other things the thread passed through the problems of heredity and genetic variation, the determination of sex, the continuity of germ cells, the problems of identical twins, and by reason of these, as well as from the nature of the cycle of life, through the embryology of neoplasms, and of cancer itself. For a long time I had imagined the cancer studies to have been an interlude in the work, but no, the thread of research passed directly through the problems of cancer. And now, quite unexpectedly, the end of the thread has been reached, because portions of it had been unraveled by some of the greatest workers in science, because Louis Pasteur, one of the greatest investigators who ever lived, van't Hoff, Le Bel, and Wislicenus had lived and labored, because their researches had founded stereo-chemistry.

The present writing is simply "The End of the Thread." Like my fellow workers, I had been taught to regard the development of any of the higher animals as "direct." That is to say, from the fertilized egg a new sexual organism, a worm or a fish, a bird or a man, arose directly. From the tissues or soma of this sexual organism new reproductive products, eggs or sperms, sprang. In this way the simple cycle of "egg-sexual organism, egg-sexual organism" repeated itself *ad infinitum.* Under this, still generally accepted, conception of development the germ cells were somatic in origin, and the gradual building up (epigenesis) of a new sexual organism happened directly, when such an egg had been fertilized. Such, briefly, was the simple embryological creed, which my teachers, Milnes, Marshall, Huxley, and Carl Semper, taught. During some eight or ten of the early years of my original work this was my embryological faith, if an investigator may have any scientific creed.

Epigenesis, direct development, and a somatic origin of germ cells have now long been associated with another embryological dogma, the recapitulation theory, according to which any higher animal "climbs its own genealogical tree in the course of its development." To what lengths and depths of scientific error this latter doctrine can lead, see the fifth revised edition of Haeckel's "Evolution of Man."

My embryological faith was perfectly orthodox, when on June 14, 1888, I left the shores of Black Lake, New York, with an extensive assortment of preserved material of fish development. One of the earliest finds made after the return to the Anatomical Institute of the University of Freiburg in Breisgau was of the existence of *two* distinct and separate nervous systems in the life history of the bill-fish, *Lepidosteus osseus.* About a year later the like find of a twofold nervous apparatus was made in some other fishes and amphibians, and especially in the smooth skate, *Raja batis.*[1-2] The transient nervous apparatus of ganglion cells and nerve fibers in the skate development functioned for a time for about three months from the start out the total of *circa* seventeen, and then, quite suddenly, began to fade away, and to undergo a slow but sure degeneration.

The two nervous systems crop up again and again in my published writings since 1888, and, as indicating the import long attached to this antithesis, I find myself writing in 1905 a paper, "The Cancer Problem,"[7] opening with a recital of some of the facts in the history of the transient ganglion cells. All my original work, from 1888 down to to-day, is impregnated with facts concerning the two nervous systems, and the antithesis underlying them. The discovery of that antithesis has impelled and influenced all my work since that time.[1-7]

With the termination of the period of research marked by the publication of "The Interlude of Cancer," I recognized that my original work was approaching and tending to converge to the work of Pasteur. My researches had led finally into problems of the chemistry of the ferments, and especially of the extracellular enzymes, trypsin, and amylopsin. It is not too much to say that Pasteur had founded a science of the ferments. True, he labored for many years at the problems of intracellular enzymes, such as the yeast organism, the mould, *penicillium,* etc., and the enzymes, trypsin, and amylopsin, for a knowledge of which the world is so greatly indebted

to Corvisart[14] and Kühne[15] never entered into the sphere of Pasteur's researches.

The interesting thing is, according to his own testimony,[27] that Pasteur's work, like mine since 1888, centered in the fundamental discovery of an antithesis. Some medical investigators of Pasteur's day denied the truth of his conclusions, either on flimsy evidences or on none at all; just as happens to-day. Equally they sought to deny the scientific investigator the right to any opinion on a question regarded by them as medical, but which was really scientific. "What," cried Pasteur, "I have been engaged for twenty years in research on a subject and have no right to an opinion! And the right of verifying, controlling, discussing, and questioning belongs more especially to him, who has done nothing to clear up the matter, to one, who has just read more or less attentively my works with his feet on the mantelpiece! You say, my dear colleague, that in the actual state of science it is better to have no opinion. Ah! well! I, even I, have one, and not of sentiment, but of reason, for I have acquired the right by twenty years of assiduous work. My opinion, or better, my conviction is that in the actual state of science of which you speak spontaneous generation is a chimera, for my experiences are complete, and they all prove that spontaneous generation *is* a chimera. As to my opponents, proof in hand I have contradicted every one of their assertions, and they have never dared seriously contradict one of mine." In passing, let it be remarked that every word of this passage might be applied to happenings at the present time regarding the problems of cancer. Pasteur further explained how the whole series of his marvelous discoveries, chemical, bacteriological, or medical, hung together and formed a complete chain, *e.g.* anthrax, the pure fermentation of beer, the acetification of vinegar, the diseases of vines, the means of preventing them, and lastly, going back seventeen years, the first link in the chain of discoveries, that of the double tartrate crystals, and the facts concerning their dimorphism.[22] "The best proof that an observer is right is the uninterrupted fruitfulness of his work."

Pasteur worked for seventeen years at his chain of discoveries, and it is now nineteen years since the first link of my chain was forged. The thread each of us obtained at the start was the discovery of *the antithesis of two things*: he, the two kinds of tartrate crystals; I, the two distinct and separate nervous systems in the life cycle of a fish.

Why should all this be? What connection was there between the two facts, which, apparently, were as wide apart as the poles? The evident fact has already been referred to that in 1904 the two independent lines of work were converging, but it was more than this. It was a union. The thing which impelled Pasteur's work incited mine also. The antithesis he discovered was in reality that also found by me. The asymmetry of the naturally occurring organic compounds, like that of the tartrate crystals, was the same asymmetry as that of the two nervous systems, and the facts of both observers were based in the fundamental verity of the asymmetry of the carbon atom, first stated by van't Hoff and Le Bel.[25] Therefore, the researches and discoveries of Pasteur and the writer as fundamentally classified are chapters, long or short, in the science of stereo-chemistry. Behind the work, which culminated in and formed the real scientific basis for my recent publication on "The Interlude of Cancer," there are the researches in stereochemistry of Pasteur, van't Hoff, Le Bel, and Wislicenus, and the eternal truth of the asymmetry of the carbon atom.

It is not fitting on this occasion to write a treatise on the science of stereo-chemistry or the chemistry of space. It has long been recognized by chemists, though this fundamental scientific truth would appear to have had as little influence on physiology as upon medicine, that because the carbon atom is asymmetrical, like the pentavalent nitrogen one,[25-28] isomeric compounds may be built up in more than one direction. To take a comparatively simple instance of these isomeric compounds, the tartrate crystals of Pasteur's researches, the one is the looking glass image in crystalline form of the other. The one in solution turns the plane of polarized light to the right, is dextro-rotatory, the other to the left is levo-rotatory. The ferment of the yeast organism acts upon the levo-tartrate, that of the mould, *penicillium*, upon the dextro-tartrate. On the other hand, the yeast organism is without action on the dextro-tartrate, the *penicillium* leaves the levo-tartrate untouched. This, as Pasteur demonstrated, is one method of separating the two in a mixture. Now, it is a remarkable fact that, when any of these isomeric compounds are manufactured in the laboratory, equal amounts of the dextro- and of the levo-compounds make their appearance in the mixture. Pasteur first noted the fact that all the artificial products of the laboratories and all the sorts of minerals encountered in nature are without action on polarized light, unlike all the naturally occurring organic compounds. This has only altered since 1860, according to Duclaux,[15] in that, while chemists can manufacture certain of these compounds in mixtures of equal amounts of the isomers, they can also be separated by the action of ferments, which are specific in this direction. For other alterations see Pope,[23] and of Van't Hoff.[16] As in the two lectures Pasteur demonstrated that naturally occurring organic compounds rotate the plane of polarized light to the right or to the left, and as such are dextro- or levo-rotatory. As Duclaux writes (p. 45), "nature alone knows how to manufacture the one isomer without producing the other." "A living cell is a laboratory of dissymmetrical forces, or a dissymmetrical protoplasm, acting under the influence of the sun."

In his "Chemical Static and Dynamics," Dr. J. W. Mellor writes as follows: "It is interesting to observe that only the dextro-sugars occur in nature (?), and that these are the only sugars which can be assimilated as foodstuffs by the yeast plant. No organism capable of digesting artificially synthesized levo-sugars is known." He then quotes from Professor W. J. Pope:[23] "It would seem to follow, as a legitimate conclusion, that while d-glucose is a valuable foodstuff, we should be incapable of digesting its enantiomorphously related isomeride l-glucose. Humanity is, therefore, composed of dextro-men and dextro-women. And just as we ourselves would probably starve if provided with food enantiomorphously related to that to which we are accustomed, so, if our enantiomorphously related isomerides, the levo-men, were to come among us now, at a time when we have not yet succeeded in preparing synthetically the more important foodstuffs, we should be unable to provide them with the food necessary to keep them alive." The term "enantiomorphism" to describe the properties of the isomeric compounds was coined by Pasteur.

In Richardson's translation[25] of Pasteur's two lectures one may read (p. 27): "Perhaps this will disclose a new world to us. Who can foresee the organization that living matter would assume, if cel-

lulose were levo-rotatory, instead of being dextro-rotatory, or if the levo-rotatory albumins of the blood were to be replaced by dextro-rotatory bodies?" With the exception of this last passage the citation from Professor Pope is the sole chemical one I have encountered, in which the possible existence of an antithetic generation is indicated. One may put his words differently, that in order to exist the "levo-men" would need to be able, by means of ferments, to pull down all our food substances and to rebuild in the opposite, or enantiomorphously related, or antithetic direction. As will appear presently, unfortunately, the hypothetical "levo-men" do exist among us, and they do pull down and build up again in the opposite direction, for the "levo-men" are the cancers.

In the light of the antithetic alternation of generations and of the natural antithesis of the compounds arising in the two generations, the following passage from Professor Pope's address (p. 283) is of interest. It is also instructive, because of the generally accepted, but false views of the question: "Again, suppose that at its origin life were carried on non-enantiomorphously, and that it involved the consumption and the production only of non-enantiomorphous substances and of compensated mixtures, it may well be foreseen that a stage in development might arise when each individual, in view of the increasing complexity of his vital processes, would have to decide to use only the one enantiomorphous component of his compensated food, and so evade an otherwise necessary duplication of his digestive apparatus. Acting intelligently or fortuitously, one-half of the individuals would become dextro-beings, while the other half would become levo-individuals; the succeeding generations would thus be of two enantiomorphously related configurations." He then goes on to express his own opinion that in course of time one configuration, the weaker one, would permanently disappear. But in this opinion the facts of botanical and embryological science are not taken into account. It is, however, only necessary to make the "succeeding generations" spoken of, alternate in order to meet the scientific requirements of nature, and so to make the passage absolutely true as a statement of scientific fact. This is done by inserting in the closing passage the word "alternating," when it would read: "the succeeding generations alternating would thus be of two enantiomorphously related configurations."

Pasteur did indeed foresee that in his finds there was given the basis of a science of comparative physiology. It is sad to reflect that in 1860 he wrote as follows, and that in all the intervening years his weighty words have been ignored by physiologists and physicians alike: "I have, in fact, set up a theory of molecular asymmetry, one of the most important and wholly surprising chapters of science, which opens up a new, distant, but definite horizon for physiology." Before the present writing was penned, this horizon for physiology seemed as distant as in 1860, for, as a general rule, the facts concerning the asymmetry of the carbon atom and of the naturally occurring organic compounds find no mention in current textbooks of modern physiology.

"Who can foresee the organization that living matter would assume, if cellulose were levo-rotatory, instead of being dextro-rotatory?" Pasteur was "a mere chemist," and "not even a medical man." He was not a biologist, though most of his researches were biological, and he was not an embryologist. Had he been well versed in the biology of his own day, the suggestion of a hypothetical levo-cellulose might have opened up an immense field to his further researches. At the time he wrote Hofmeister's researches[17] on the life histories of various plants, with the main facts concerning the alternation of generations therein observed, were already the possession of science.* If there be a dextro-cellulose, or a levo-albumin, or a dextro-sugar, or a dextro-glycogen, stereochemistry asserts the possibility or the necessity of the occurrence of a levo-cellulose, a dextro-albumin, a levo-sugar, a levo-glycogen. This the reader will find laid down on page 14 of Meyerhoffer's German translation of van't Hoff's work. Duclaux[15] rightly observes that to obtain the change from the one direction of asymmetry to the other, it is necessary to go back to the "germ." Like the cellulose of a flowering plant, a rose, or an oak tree, that of the fern-plant is dextro-cellulose. But in the life-cycle of the fern, as in that of the flowering plant, there are two generations, the asexual one, or fern-plant, and the sexual one, the small and insignificant prothallus. As the cellulose of the fern is dextro-cellulose, so that of the latter must be levo-cellulose, and so with the other naturally occurring organic compounds. None such found naturally in an asexual generation of a plant, or in a sexual generation of an animal, will be met with in the corresponding sexual generation of a plant or asexual generation of an animal, but, if occurring at all, it will be represented by a compound with the opposite rotation. The reason is because the carbon atom (like the pentavalent nitrogen one) is asymmetrical.

The cycle of life, animal or vegetable, is asymmetrical, because the antithetic alternation of generations underlying it is founded on the asymmetry of these atoms. The generations, sexual or asexual, alternate according as the compounds are built up in the one direction or the other, for at its basis development is the building up of naturally occurring compounds. In both animals and plants enzymes or ferments are the chief actors in this. The new organism, whether animal or plant, destroys that upon which it arose, and builds up in the opposite direction. The birth of the new fern-plant implies the destruction of the prothallus. The embryo or sexual generation of a mammal, or a man, destroys the asexual generation, the trophoblast, or chorion, upon which it arose, and builds up its compounds in the opposite direction to that employed by the latter. So also the cancer. This irresponsible trophoblast or asexual generation destroys the naturally occurring organic compounds and the organism upon which it arose, and builds up in the opposite direction.

The action of a ferment is always a specific one. It fits the substance upon which it acts, "as a key fits a lock" (Emil Fischer). Other substances it leaves untouched, even isomeric or compounds having an opposite rotation. Dr. Margaret A. Cleaves[13] wrote in the MEDICAL RECORD of June 1, 1907, "It is probable that enzymes are

*In his History of Botany the late Professor Julius von Sachs writes in terms of eloquence and admiration of Hofmeister's researches. "The result of these 'Comparative Investigations, 1851,' was of such grandeur as in the realm of descriptive botany has not since happened a second time." He speaks of "the brilliance of the grand sum total, 'alternation of generations' had proved itself to be the highest law of development in plants, governing the whole long series." He dilates on "the grand picture which Hofmeister had drawn of the genetic connections of the members of the Plant Kingdom." What the zoologists were to experience fifty years later, viz., an antithetic alternation of generations in animals as *the law* of their developmental cycles, was unraveled for plants by Wilhelm Hofmeister, nine years before Pasteur gave the two lectures "On the Asymmetry of the Naturally Occurring Organic Compounds," and before he uttered the prophetic words, "Who can foresee the organization that living matter would assume if cellulose were levorotatory instead of being dextrorotary?"

of stereo-chemical configuration in their construction; that is, that they are built upon a central element having a definite valence, and hence, that all enzymes are capable of entering into chemical action with only those substances that attract and have an opposite isomeric form." Confining one's attention to cancer, the cancer-ferment, malignin, acts upon and pulls down the levo-albumins of the living human body. I have stated with von Leyden,[20] Blumenthal,[12] and Bergell,[10] more recently confirmed by Neuberg and Ascher, that the action of trypsin on the living albumin of cancer is specific. Quoting further from Dr. Cleaves, "the only possible explanation of the effect of trypsin on pathological conditions capable of giving a tryptic reaction must be that certain proteid molecules, *e.g.* in cancerous conditions, are capable of being attacked by trypsin, because of their special configuration." In other words, the conclusion (foreseen by Dr. Cleaves also) may be drawn that the albumin or albumins of cancer are dextro-rotatory. All this has been denied—without evidences beyond bald assertion—by various "authorities," official researchers, and medical journalists. As the levo-albumins of the living human body are not acted upon by trypsin, whereas the albumins of a living cancer are, it follows, as day succeeds night, that the latter must be dextro-albumins. No amount of contradiction in official reports or in medical newspapers can ever alter the truth of this fact, for "all enzymes are capable of entering into chemical action with only those substances which attract and have the opposite isomeric form."

Much has been written about glycogen in tumors. Brault thought that the malignancy of a tumor varied directly as its richness in glycogen. Another investigator, impressed with this view, sought some substance which would "break up" this glycogen of a tumor, and hit upon trypsin. But the curious thing is that not only, of course, has trypsin no action upon the glycogen of a cancer, but the like is true of amylopsin. The latter at once converts the dextro-glycogen of the liver, but, as Dr. Cleaves has shown in her paper already cited, amylopsin has no action upon the glycogen occurring naturally in a cancer. The reason is because the latter glycogen is a levo- one. The interpretation to be placed upon the leucocytic phenomena of the Cleaves "trypto-glycogenic reaction" (the enormous increase of the eosinophile leucocytes under the enzyme treatment of cancer and their attraction by the glycogen of the tumor) is that amylopsin leaves the glycogen of a cancer untouched, but that it stimulates the leucocytes to seize it and to invert it. Just as isomeric compounds in the form of starches occur in both generations of plants, so also isomeric compounds of glycogen or animal starch are found in sexual and asexual generations of animals, including cancer. But if the dextro-compound occurs naturally in the one generation, the levo- one will obtain in the other. Mellor remarks (p. 364) that only the dextro-sugars or glucoses are known to occur naturally. This is because the chemical composition of the sexual generation of any plant, a fern prothallus for example, has never yet been determined in the laboratory. It is not true of animal life, for as long ago as 1855, Claude Bernard[11] found levulose or levo sugar in "the allantois." According to him (p. 398) it disappears towards the fifth or sixth month of intrauterine life of the calf, a fact which goes to show this levo-sugar to be formed in the trophoblast, and not in the allantois. Doubtless, its disappearance coincides with the development of large numbers of leucocytes in the fetus. To my knowledge this levo-sugar has more recently been rediscovered "in the placenta," but I am not aware that the fact has been republished. Of course, the "allantois" and the "placenta" are synonymous, but the real source of the levulose in both instances was asexual generation or trophoblast.

The asymmetrical carbon atom, like its colleague, the pentavalent nitrogen one, has hitherto found as little place or mention in medicine or in physiology, as has an antithetic alternation of generations. Man has thus found it possible to dispense with things and phenomena, indispensable to Nature, and but for which he would have no existence! Whatever matter may be, whatever the nature of what we term "living matter," at the basis of life lies the fundamental facts of the asymmetrical carbon atom and the isomeric compounds. At the base of all animal or plant life, too, because of these facts, there rests the antithetic alternation of generations. With the start of the asexual or the sexual phase of the cycle, the naturally occurring compounds are built up in the one direction or in the other. With the beginning of the next phase of the cycle, the alternate one, sexual or asexual, the swing of the pendulum about the asymmetrical carbon atom is on the other side, and the naturally occurring organic compounds are built up in the opposite direction. In animal life, that of the higher animals, the compounds are built up after the fertilization of the egg, and in the life-period of the asexual generation in the direction of levo-sugar, levo-glycogen, and dextro-albumins. This evolution of compounds is the antithesis of that which obtains with the unfolding of the sexual generation, "the embryo" or individual. Here the naturally occurring organic compounds are evolved in the direction of dextro-sugars, dextro-glycogen, and levo-albumins. It is of great interest to compare together animals and plants in this connection. As I wrote some years ago,[6] "the plan carried out in animals has been such as to favor the ever greater and greater amplification of the sexual generation. In plants, as elsewhere already insisted, the reverse is the case. Here the asexual generation has undergone increased amplification without ever being able to attain to any very high degree of histological differentiation. The sexual generation of plants is at the best a miserable failure from the morphological point of view, and this must be set down to the factors indicated, and still more to others to be yet described. The higher one ascends, the smaller it becomes, until, in the highest flowering plants, it has almost reached the vanishing point, without, however, being able to disappear entirely. In animals it is the phorozoon or asexual generation which makes the bravest show in the lower metazoa; but even here it is usually overshadowed in degree of morphological differentiation by the embryo or sexual generation. In the higher forms it becomes reduced; but, like the rudimentary sexual generation of the higher plants, *it cannot vanish, for it also has its assigned task in the reproductive round.*" The scientific investigator does not, of course, deal in *a priori* arguments. Were he to do so he would expect to find the conditions exactly the same in plants as in animals. For is it not "generally held," and for this reason scientifically correct, that animals and plants have a common ancestry? Do not zoologists and botanists agree that at the bottom of the scale animals and plants merge together, and that some of the lower organisms may be described equally well as animals or as plants? The scientific truth of the matter is *that there is no merging together of the two kingdoms.* Such a blending is impossible, because the carbon atom is asymmetrical. None the

less, the asymmetrical carbon atom vouches the unity of organic Nature.

It is clear that, if in any group of organisms, animals, plants, bacteria, fungi, etc., there be two phases of the life-cycle, asexual and sexual, there are for any given case two directions in which the naturally occurring organic compounds can be built up. But it should not be forgotten that the number of possible isomeric compounds increases with their complexity. The sexual generation of animals is characterized by dextro-sugars, dextro-glycogen, and levo-albumins. In the corresponding sexual generation of plants, such as the fern-prothallus, these are absent, being replaced by enantiomorphous compounds with the opposite rotations. It is the asexual generation of plants, the flowering plant, and not the sexual generation, which possesses dextro-sugar, dextro-starch, and levo-albumins. The harmony of this is twofold. It realizes the apparent possibilities, and from the point of view of animal life it is of overwhelming importance that it should be so. Ultimately, of course, all animals are dependent on plants for their food-stuffs. Were the sexual generations of plants the producers of the food-stuffs of animals, the latter, owing to the insignificance of the former, would find existence a very serious problem. The sexual generations of plants form substances resembling those fabricated by the asexual generations of animals, trophoblast, or cancer. Even if obtainable in sufficiently large quantities, the substances found naturally in a cancer would not be suitable as the food-stuffs of an animal, a man for example. But, as the asexual mode of reproduction, whether of a plant or of a cancer, is the more prolific one, there has been hitherto, at all events, no failure on the parts of the asexual generations of plants to furnish ultimately the food-stuffs of the animals. The conditions met with in animals are reversed in plants. Here a levo-cellulose, a levo-sugar, a levo-starch, and one or more dextro-albumins must be sought for, *not* in the asexual generation as in animals, but in the sexual one, as represented by, for example, the fern-prothallus. "Science is prevision," said Pasteur. Because of the truth of this one is able to set up the following table of comparisons.

ANIMAL.	
Sexual generation or individual.	Asexual generation, trophoblast, or cancer.
Levo-albumins, not acted upon when living by trypsin and amylopsin, but attacked in life and pulled down by the cancer-ferment, malignin.	Dextro-albumins, not acted upon when living by their own intracellular ferment, malignin, but attacked in life by trypsin and amylopsin.
Dextro-sugars.	Levo-sugar.
Dextro-glycogen.	Levo-glycogen.
Pigment melanin.	Pigment not melanin (in melanosarcoma, Blumenthal).
PLANT.	
Asexual generation (flowering plant or fern).	Sexual generation (fern-prothallus).
Levo-albumins.	Dextro-albumin.
Dextro-starch.	Levo-starch.
Dextro-sugars.	Levo-sugars.

It would be interesting, were sufficient information available, to inquire into the conditions met with in bacteria and fungi. These are fundamentally neither animals nor plants. So far as the facts are known regarding their compounds and their ferments, some of them seem to resemble the asexual generation of animals, rather than that of plants. In given circumstances many of them can attack the compounds of the sexual generations of animals, or of the asexual generation of plants, pulling them down and building up in an opposite direction. As the plants and the animals are not genetically connected, so also, in all probability, the bacteria and the fungi have no genetic relationships with each other, or with the animals or the plants. Like the two latter they are separate evolutions.

In 1889, in his study of the placentation of the hedgehog, *Erinaceus europæus*, Professor A. A. W. Hubrecht[18] set up the term "trophoblast" (p. 298), at the same time assigning to it, as the name implies, a nutritive significance. The nutritive import of the trophoblast of normal mammalian gestation has since that time been confirmed by many other embryologists, notably by Professors E. van Beneden and M. Duval, and it has been "generally accepted." In the light of our present knowledge a significance different from that seen in it by Professor Hubrecht must be recognized in "trophoblast." Trophoblast has, and can have, no nutritive import for the developing embryo. This is quite obvious, once it is noted that the natural compounds formed in it are built up in the wrong direction to be useful as food for the developing sexual organism. The term, therefore, cannot be employed in future in a physiological sense. As Duclaux said: "Nature alone knows how to manufacture the one isomer without producing the other." The chemist in the laboratory manufactures equal amounts of both isomers. May one deny Nature the power to do the like on occasion? Certainly not. It must be concluded that in the fertilized egg she can build up in both directions. By the first few cleavages of the egg, usually the first three to five, she can separate off portions as cells, endowed solely with the powers of producing the isomeric compounds of trophoblast, while retaining for the cell in the line of heredity the property of forming both. With the start of the evolution of an embryonic body, again by cell-division, she can separate off one or more original embryonic cells with powers the opposites of those possesesd by trophoblast, all this taking place before any extracellular enzymes, such as trypsin and amylopsin, are formed. Full agreement, therefore (in a sense), may be expressed with the conclusion of Duclaux, that "to introduce in a cell principles immediately different, and the inverse of those which existed there, it is necessary to act upon it at the moment when it is most plastic, to take the cell of the germ, and try to modify it" (p. 66). But, as Duclaux also observes, this cell has a heredity, and this determines not only its being, but what it shall become.

As may be gathered from the foregoing, the enzyme treatment of cancer professes to be, and is, a scientific one. Mankind in general and surgeons in particular, have long looked for a cure for cancer. Presumably, this was to replace the knife. Now, at last, science and scientific research have offered not *a cure*, but the scientific treatment of and *the cure* for cancer.* At once the surgical demand was altered into the request for a cure after the fact of operation on the living cancer. Scientifically, this demand cannot be met. Cancer is a natural phenomenon, not a disease. To "operate" upon living asexual generation is unnatural. As a scientific remedy the enzyme treatment of cancer

*This statement might seem to be at variance with a report from Copenhagen on page 490 of the MEDICAL RECORD of September 21. Here in seven lines there were compressed the adverse results of the treatment by "trypsin" of not fewer than ten cases of cancer. The cases were not described, but, waiving the point of absence of the histories of the cases, another matter must be mentioned. Preparations of "trypsin" for injection have been made up and placed on the market by chemists. These injections are prepared from trypsin in powder, which contain diastase, derived from grain, not from pancreas-gland. Preparations, made up from trypsin in powder, or containing plant-diastase, instead of amylopsin, are not suitable for the treatment of cancer by enzymes. No such injections have yet cured one of the published cases. Indeed, all these have been treated with injections prepared from the fresh gland direct.

makes no claim to be the cure for cancer after it has been interfered with operatively once or oftener. As a natural treatment, it is not intended for post-operative "inoperable" recurrent cases. Did surgeons know that cancer was in its nature asexual generation, *they would never touch a living cancer with the knife.* For it is the property of asexual generation, animal or vegetable, that it can be subdivided indefinitely. In evidence of this fact one need only refer to all the inoculations of cancer which, starting from one original mouse-tumor, have been made into other mice. But one may also cite the very numerous observations made in recent years in what has been termed "experimental embryology, but which would be designated more correctly "experimental pathology." Very numerous observations in this unnatural subject will be found in the twenty-four volumes of the *Archiv für Entwicklungsmechanik,* in the *Journal of Experimental Zoology,* and elsewhere. Many of the observations were made upon fertilized eggs in cleavage, and they were almost as successful in subdividing the asexual generation represented by an egg in cleavage, as are the gardener's proceedings in making and rooting cuttings from a chrysanthemum plant. The student of all these published experiments will notice that the organisms experimented upon never reverted to the normal. These experiments proclaim the truth of the statement that by operation a living cancer may be, and usually is, subdivided indefinitely. Moreover, let the words of the Professor of Medicine in the University of Berlin be recalled: "A cancer reacts by increased growth to any injury, mechanical, chemical, or thermal." As a rule, not free from exceptions, in my experience, while absolutely unoperated cases, if not too advanced, invariably do well under the treatment, cases where there was previously operative interference cannot be guaranteed, and by me *are not indorsed as likely to be successful.* Nature does not "operate" upon living asexual generation, and perhaps for this reason she has not evolved an infallible mode of treating scientifically the failures of surgical operation. Dr. Rice's case[24] of laryngeal cancer may be cited as an instance of the successful treatment of an unoperated tumor, as also the Naples case of inoperable cancer of the tongue.[8] Within the past few days another case of the like kind has been reported privately as cured. Here in October, 1906, on operation a leading London surgeon found an inoperable cancer of the cecum. He made no attempt to remove it. In December the enzyme treatment was commenced, and continued until April, when on examination this surgeon pronounced it "almost a cure." Now, in August, the cancer has quite disappeared. This unreported case is paralleled by one in the *British Medical Journal* of August 31, 1907, p. 541. The like history is true of many other cases. But with post-operative recurrent cases, while there may be success, as in Dr. Wiggin's case,[20] since certified as cured, the cancer is more likely to "run its parabola" than to yield to a scientific treatment.

When authorized investigators are heard proclaiming to mankind that the enzymes, trypsin, and amylopsin have no action upon living cancer-cells, this is not merely a denial of the truth and validity of all my embryological work of the past nineteen years. (That is nothing new. Were it to-day a new scientific discovery, that "two and two make four," its truth would be challenged!) But by such negations the fundamental truths of the science of stereochemistry are also impugned, as well as the asymmetry of carbon atom. In short, when the efficacy of the enzyme treatment of cancer is questioned or denied, the constitution of the visible universe is condemned.

"Sooner or later a conviction may dawn upon investigators that the laws governing animal development lie deep, and that to discover them we must also take wider and more comprehensive views of our problems. Moreover, it should not be forgotten that little things, like a few stray ganglion cells, may hide an all-important story, and that here, as elsewhere, in the apparent exception itself the key to the mystery often lies concealed."

PTOSIS OF THE ABDOMINAL VISCERA SURGICALLY CONSIDERED.

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

Heredity has frequently been considered as a predisposing cause for ptosis of the abdominal viscera, and this opinion has been upheld by a number of French and German authorities, who explain it by a congenital inferiority of the tissues, the organs of nutrition, and the nervous system. Alcoholism, syphilis, overwork, venereal excess, and physiological misery in the parents are considered as the principal causes predisposing children to ptoses. In 1896 Stiller established a rather peculiar relationship between abdominal ptoses and an abnormal mobility of the anterior tip of the tenth rib, and according to his way of thinking it is due to a congenital ligamentous insufficiency. At the same time the skeleton will be found gracile, the intercostal spaces very broad, muscular development poor, likewise that of the cellular tissue; in other words, the patient represents a generalized congenital asthenia. In 1901 Cseri pointed out that patients afflicted with abdominal ptosis presented a tendency to the development of lordosis, which resulted in a diminution of pressure from below upwards. Glenard does not deny hereditary predisposition, but he believes that it is rare, and in 11 per cent. of the cases under his observation it appeared to him rather more due to poor hepatic functioning than to a defective condition of the nervous system.

Traumatism alone rarely produces ptosis, but in a person predisposed an injury may be the productive cause. Horsemanship, dancing, vomiting, and other violent efforts may give rise to it. In Glenard's statistics limited to cases where gastroptosis coexisted with nephroptosis and hepatoptosis, we note that a traumatism in the form of a fall or a violent effort was incriminated twenty-two times in women getting up from their labors, and only twice was it found without this predisposing cause.

All these causes are consequently not exclusive, but rather more of an accessory nature, one becoming combined with the other in order to produce a condition which either one alone could not. But, beside these accessory causes there is still another which is far more important and more general, namely this badly defined disturbance of the nutrition showing itself by a particular condition of the fibrous tissue allowing itself to become distended, to poorly resist constant fatigue and prolonged efforts. It is this predisposition which in the male results in the production of hernia and in the female to eventration, and in both sexes to varices, movable kidney, and hepatoptosis. In a word, heredity plays the principal part, and traumatism, no matter of what nature, only acts secondarily, just as it frequently does in the production of a tuberculous arthritis in a predisposed subject.

As an occasional cause in the female, pregnancy and labor play a large part. The former acts either by the infections which may succeed it, but more especially by the changes that it produces in the abdominal walls by modifying their previous tonicity and producing ulterior distention. Opinions vary as to whether or not pregnancy has any real influence on the production of visceral ptosis and numerous authorities, among whom we may mention Glénard, Faure, and Landau, recognize that frequently the ptosis declares itself after a normal pregnancy, while upon other occasions the first symptoms show themselves during labor. On the other hand, Brault, Linder, and Kuttner have pointed out that movable kidney is found in the nulliparous and in men quite as much, if not more so, than in multiparous females, and consequently deny any influence in the production of this condition arising from pregnancy. Linder has published the following statistics relative to nephroptosis: 24 nulliparous, 10 primiparous, and 30 multiparous females, while Kuttner found 40 nulliparous, 10 primiparous and 44 multiparous females. This same authority found that out of 39 cases of gastroptosis there were 10 nulliparous, 12 primiparous, and 17 multiparous females. I believe, however, that, although these two authorities have not admitted the pathogenic action of pregnancy, it may, however, be supposed that the support given by the abdominal walls must have been insufficient, and if this insufficiency can arise without pregnancy coming into play, it does not at all imply that the latter, by its dystrophic action, cannot be the cause of ptoses which would not have occurred without this adjuvant cause. I would also point out that here predisposition plays an important part, and that, if one meets with patients who, after their first pregnancy, have a lax abdominal wall, there are, on the contrary, many others who have been many times pregnant without any change taking place in this structure.

Eventration results from a diastasis of the recti, so that pregnancy, or large pelvic tumors, which considerably distend the abdomen, or a laparotomy incision, which has weakened the anatomical structures uniting the recti and their aponeuroses, are frequently causative factors.

Now, in point of fact, what is the true influence of eventration on the production of prolapsus of the various abdominal viscera? Landau admits that nine times out of ten one is dealing with women who have had several confinements. Their abdominal wall is lax, thin, the abdomen falls forward and downward, and this pendulous abdomen is one of the most important causative factors in the production of ptoses. It is evident that tension of the abdominal muscles must play a very great part in the statics of the intestine, because in the normal condition, that is to say, tense and resistant, the abdominal wall opposes falling of the intestine, holding them up, and the former acts like a cushion on which the liver, kidneys, and spleen lie. If the abdominal walls become relaxed, especially if the pelvic floor is also defective, the weight of the contents will be more greatly felt, and will produce an elongation of the supporting ligaments of the various organs.

Now, can the law of gravity alone suffice to produce this elongation? I believe that this is to be doubted, and I would say that this elongation is only really possible if we admit an inherent weakness of the tissues, a disturbance of the general nutrition, acting at the same time on the abdominal wall and the ligamentous folds. Schwerdt also attributes a great part to the decrease of intraabdominal pressure, and he points out that in a normal abdomen there exists a certain tension, which, according to his observations, is equal to a column of water eleven centimeters high, and which he terms the tension pressure. Beside this there is also a surcharge pressure, due to the fact that the abdominal organs obey the law of gravity, and from his manometric experiments he proved that the tension pressure and the surcharge pressure are inverse to each other.

Glénard has criticised this theory and only attributes a secondary part to this abdominal hypostasis. He places intestinal ptosis foremost and only con-

siders hypostasis as a predisposing cause, or when once the ptosis has occurred he considers it as merely a complicating cause. Then considering feminine etiology more particularly and especially the puerperal origin of enteroptosis and the predisposing condition created by a decrease of the abdominal tension, he shows that it is far more to a sudden decrease of the abdominal contents than to an increase of its absolute capacity that the dangers of this diminution of tension are to be attributed. He, however, does not recognize the importance of a defective tonicity of the anterior abdominal wall, which, following acute infectious diseases or large abdominal tumors, becomes thin and weak, so that they may easily become distended. In discussing Landau's theory, Faure, without, however, discarding the influence of eventration, says that the German authority has given a too exclusive importance to eventration and that it would be more exact to say that, if a pendulous abdomen often accompanies ptoses, or favors their production, it is quite incapable of giving rise to them. In other terms there is not a relation of cause and effect between the displacement of various organs, but both these accidents are under the dependence of a more general cause which is quite sufficient in itself to produce them, either at the same time or independently one from the other.

Large abdominal tumors, such as an ovarian cyst, fibroid, or ascites, act in the same way as pregnancy, because they overdistend the recti and consequently may produce ptoses in predisposed subjects. As to laparotomy incisions they only give rise to ptoses when the abdominal wall has been badly approximated when closed after an operation, or the patients have been allowed to get up too soon, which has resulted in distention of the cicatrix, with the resulting thinning.

Ptoses are met with in men quite as much as in the female, but the latter are more predisposed to this condition on account of pregnancy, sedentary life, a weaker muscular system, and a more irritable nervous system, and women certainly offer the greater number of cases of enteroptoses. Glénard found 70 women and 30 men out of a total of 100 cases of coecal prolapse and in 100 cases of gastroptosis the proportion was the same. Nephroptosis is probably still more frequent in the female than in the male. According to Landau, there were 275 renal ectopias in the female against 41 in the male, while Kuttner found 584 cases in women and 82 in men. Uniting these and other statistics, Bruhl found 1,028 ectopias in the female and only 148 in the male. As far as splenoptosis is concerned, Glénard collected 14 cases, 11 being female and 3 men. The same may be said of hepatoptosis, which is represented by 2 per cent. in the male and 13 per cent. in the female and out of 100 cases Glénard found 86 women and 14 men. According to Landau the proportion of hepatoptoses in the male to that found in the female is as 1 is to 23.

Corsets as a causative factor of ptoses has given rise to lengthy discussions, and it has been questioned whether or not by the constriction that they produce on the costal wall and the resulting deformity to which it gives rise, by pushing the abdominal viscera from their anatomical situations, they might give rise to ptoses. It is quite evident that the results from constriction must be very variable because they will naturally depend on the conformation of the thorax and the shape of the apparatus itself and the way that it is worn.

Havem and Lion have divided the cases of ptosis into three classes. In the first there is suprahepatic or inframammary constriction, with ptosis, the organs being pushed downwards. This variety sets up static disorders and produces the ptoses, exercising as it does its action over the diaphragmatic vault, the compression produced by the corsets is more marked on the convex aspect of the liver, which is pushed downwards and, at the same time, all the abdominal viscera as well and, according to Hayem, this represents the classical "corset disease." In the second type there is hepatic constriction as well as of the other organs, which are elongated and deformed, although ptosis need not necessarily be present. The third variety represents infrahepatic constriction in which the viscera are pushed upwards. Hertz, Voeglsang and others uphold that, by immoderate constriction a very marked narrowing of the supraumbilical region of the abdomen is produced, with an exaggerated development of the infraumbilical region which forms a pocket, so to speak, into which the stomach, intestine and colon are pushed.

As far back as 1853 Bouvier pointed out that the corset was not always to blame, and he says: "Le corset moderne peut bien, il est vrai, lorsqu'il est serré outre mesure ou que les parties rigides qu'il contient exercent des pressions exagérées, provoquer accidents nombreux, mais n'est-on pas entraîné par les anciennes préventions à lui attribuer bien des déviations à type normal dont il n'est pas responsable?" A number of authorities continued his work and Faure says that he would be inclined to say that corsets have been unjustly incriminated, because physicians in general have never thoroughly examined their shape and the way they are applied, and speaking of the pathogenesis of movable liver, especially as far as the action of corsets is concerned, he says: "Les corsets de tout genre et de tout mode s'appliquent par leur point le plus rétréci très exactement à la taille, immédiatemment au-dessus de la hanche c'est-à-dire de la crête iliaque, en dessous du rebord costal. La constriction de l'abdomen, lorsque le corset est serré, se fait donc en avant et tout au-dessous des côtes et par conséquent au-dessous du foie. Il tend donc à soutenir le foie, à le soulever même et non à l'abaisser. Il ne peut avoir cette dernière influence que lorsque le foie est déjà descendu et c'est dans ce cas qu'on rencontre surtout sur la surface l'empreinte du corset, empreinte qui ne saurait évidemment se transmettre à travers la cuirasse costale. Il est donc très probable que les cas assez nombreux où l'on a signalé une déformation de foie sous l'influence du corset étaient eux aussi des cas d'hépatoptose qui ont été mal observés."

We may consequently conclude that the deformity of the liver explains its ptosis, but the many causes which may produce its deformity and ptosis are particularly decreased in the abdominal tension and intrahepatic tension. Corsets act especially by constriction when the liver has already become displaced and the special deformity found should merely be considered as a simple modality of a general process. And still corsets push the liver down, since they deform it, and according to Glénard the deformity cannot arise without prolapsus. But in this prolapsus produced by corsets the lower border of the liver does not reach below the costal border and this is due to the fact that the deformity and ptosis of the liver are produced by the deformity and lowering of the base of the thorax, and these two conditions are always in direct relation as far as their intensity is concerned.

From birth one may note a ptosic temperament in a given subject, and, when speaking of heredity, I pointed out that Stiller had demonstrated the relations existing between abnormal mobility of the

anterior end of the tenth rib and in lividuals predisposed to ptoses, and that Ceri had also shown a tendency towards lordosis.

Beside visceral ptoses, children under the influence of this diathesis frequently present prolapsus of the rectal mucosa resulting from a defective tonicity of the sphincter ani; their tissues are soft and the scrotum is elongated. They are subject to chapped hands, and so forth, due to vascular ptoses, and very frequently they present congenital hernia or renal ectopia. All these facts uphold the theory of heredity, and the ptosic diathesis would appear to be due to a kind of congenital weakness of the nervous centers.

It is between the ages of 20 to 40 years that the larger number of visceral ptoses are met with, and it is towards the middle age of life that women show various forms of prolapsus. Women who will suffer from ptosis sooner or later have very easy labors, sometimes with hardly any pain, and the proof of this temperament in these patients is shown by the extreme laxity of the abdominal walls after labor, while they are also subject to hemorrhages due to atony of the uterine muscle, while the uterus has a great tendency to become displaced backwards. As time goes on all forms of ptosis become accentuated, and it is between the ages of 50 to 60 years that the most marked forms of eventration are met with. Senility attacks the nervous system, the muscles become atrophied and undergo fatty degeneration, while the development of the ptosis at this time of life shows the influence of the muscular tonus, which is inevitably insufficient at this age.

Visceral ptoses are rarely single, and it is of common occurrence to find enteroptosis and nephroptosis combined. Movable kidney is met with in about 18 per cent. of subjects not having intestinal ptosis, while this renal condition is found in about 30 per cent. of those presenting the latter condition. One finds movable kidney in 60 per cent. of patients suffering from enteroptoses. Transverse ptosis and movable liver are combined in about 61 per cent. of cases of hepatoptosis, and very frequently nephroptosis is met with in cases of movable liver, about 25 per cent. according to Antoine. Out of 100 cases of nephroptosis the same authority states that there was ptosis of the liver in 45. Ptosis of the spleen is rarely met with associated with that of the liver, but this is simply due to the infrequency of the former condition. A remarkable fact, however, has been pointed by Antoine, namely, that out of 100 hepatoptoses there were only 5 splenoptoses, while out of 100 splenoptoses there were 100 hepatoptoses. Consequently, ptoses of the spleen do not exist without hepatoptoses. The same may be said of splenonephroptosis, which always accompanies ptosis of the liver.

Nervous and hepatic disturbances are the two factors, which, according to various authorities, act differently. All have noted the coincidence of nervous disturbances with ptoses, but while some uphold that the nervous conditions are the result of the ptoses, others have reversed the proposition and believe that the ptoses are the result of the nervous disturbances. It is, I believe, an evident fact for everybody that nervous heredity plays a very important part in these cases. Glénard has also considered the functional weakness of the liver, and places nervous conditions as secondary, the primary cause acting directly on the liver, whether this cause be of an infectious, toxic, nervous, or traumatic nature, it matters not, the disturbance of the nutrition persists and brings about a functional weakness of the organ. The subject then becomes a diasthesic, and from this time on he will be the possessor of an "hepatic temperament." This "hepatism" may be either infectious or hereditary, but however this may be, it will be the endogenic factor of other diseases of the nutrition, like enteroptosis, etc. Which of these theories are right is impossible for me to decide.

If patients the subjects of ptoses are questioned as to their morbid antecedents one will frequently note that the condition has made its appearance after some serious infection, such as typhoid, scarlet fever, influenza, etc. Convalescence was long, the loss of flesh great, the general condition thereby consequently changed, while the nervous system or the liver were affected by the toxins, and from all this results a general dystrophia, which gives rise to ptoses.

My personal observation would lead me to believe that labor contributes the largest share in the production of visceral ptoses. During pregnancy the abdomen is for the greater part of the time insufficiently upheld, and an elastic binder or a special corset would, to a certain extent, prevent the excessive distention of the muscles and the skin. On the other hand, after labor, sufficient care is not given to properly apply the binder and to continue its use for a sufficient length of time. Women usually get up too soon, and the abdominal walls undergo pressure at a too early date which they are incapable of resisting. Then, again, sufficient attention to laceration of the perineum is not given, and, although the latter may be small, it should, according to my way of thinking, be immediately repaired.

Surgical interference I believe only legitimate in those cases where all other means have proved unsuccessful, or where the patient's life is rendered miserable by the condition. In order to be sure that the operation is successful in its results, I employ the following technique: The patient is placed flat on the operating table, or very slightly tipped up, so that the position will not allow the prolapsed organs to return to their normal position. An assistant then grasps the abdominal wall with both hands, so as to tighten it as much as possible. Then, by palpation and percussion, the surgeon ascertains if the kidney, liver, and stomach have undergone any notable ascension. Since the operation has for an end to tighten the abdominal wall, it is performed as follows: An incision, starting a little below the point of the sternum, is carried down to the pubis, and the aponeurosis of the recti is exposed and is then dissected to the extent of about one-third of its length. The posterior aspect of the recti is then exposed to the extent of about 2 centimeters in breadth. A row of continued kangaroo tendon sutures unites the recti by overlapping them. After having resected the excess of the anterior aponeurosis, a second laver of kangaroo tendon unites this. Then, by an elliptical incision, all the skin that is necessary should be removed and the borders brought together by silkworm gut sutures.

I have resorted seven times to this operation successfully in very desperate cases of ptosis, and so far as I am aware no recurrence has ever taken place. The patients varied between 37 to 58 years of age, and all made uneventful recoveries. Some of them were hard-working women with large families to care for, and as they have remained in very good health ever since, attending to their arduous duties, they would seem to speak decidedly in favor of the operation. Then, again, since the peritoneum is not opened the interference may be considered as absolutely devoid of any danger whatsoever.

871 Beacon Street.

ADVANCED AGE AS A CONTRAINDICATION TO OPERATION.*

By OLIVER C. SMITH, M.D.,

HARTFORD, CONN.

SURGEON TO HARTFORD HOSPITAL.

A WHOLESOME dread among the medical profession and an inherited, long-existing prejudice among the laity has ever been the attitude toward surgical operations among the aged. It is unnecessary to say that elective operations, unless it is quite certain they may prolong life and increase comfort or usefulness, are not to be urged upon patients far advanced in years; but emergencies which threaten life, and conditions productive of suffering and incapacity, making the life miserable while it lasts, not infrequently demand surgical interference as promptly and as surely in the aged as in the young.

In deciding for or aginst operation we depend upon the condition of the heart, the arteries, the lungs, and kidneys, rather more than upon the number of years the patient has lived. The potential age is the factor of importance. The individual may be young in vital tissues, while the actual age is advanced, and vice versa. Modern methods of technique, including careful hemostasis, rigid asepsis, gentle handling of viscera, local anesthesia, or general anesthesia by the ether drop method, and the prevention of shock, have placed surgery of the aged upon a far safer plane than it has occupied in times past.

Aged people do not tolerate well the loss of blood, and in surgical work upon them we should adopt those measures which are calculated to control hemorrhage before it occurs. These measures include the use of the Esmarch bandage, of proper posture, of segregation as practised by Dawbarn and Crile, of clamping and ligating vessels on either side before they are severed, hot gauze and hemostatic packing in locations where the vessels are not susceptible of ligation. Prominent among these hemostatic remedies may be mentioned solutions of adrenalin chloride and formaldehyde gelatin.

Asepsis should include careful and thorough preparation of the parts, for the senile skin is frequently thick and scaly; careful avoidance of crushing of tissues by forceps or ligatures drawn too tightly, and the use of correct methods of personal and operative cleanliness.

In the handling of viscera in the abdominal cavity it is important to avoid injuring the serosa, to grasp the tissues with soft, moist serviettes or with the gloved hand, to use as little traction as possible, to guard against pinching and bruising, producing hemorrhage or ecchymoses, for there cannot be quite the power of resistance, repair, or absorption in patients of advanced years as in those of middle life or youth. Explorations in the abdominal cavity should be carried out deftly and with dispatch. In the language of another, the motto in operating upon these patients should be that of "bloodless surgery and breathless speed."

The anesthesia is a very important matter. Too frequently this importance is under-estimated and the anesthesia is considered too lightly. It is well known that many operations for which general anesthesia is usually administered may be comfortably and safely performed with some local anesthetic. With such we have frequently done perineal sections and drained the male bladder; we have operated for strangulated hernia, appendicitis, and performed minor amputations. I am not in a position to advocate strongly spinal anesthesia, although we have used it in a number of cases. It carries with it certain unfortunate sequelæ, and has not grown in favor in this section, at least during the past two years. For general anesthesia I have become wedded to the use of ether by the drop method. Prior to May 1, 1906, we had used it occasionally according to the rules observed at the Mayo clinic, and since that time we have used it exclusively in cases where ether was not contraindicated. The average time for complete anesthesia has been eight minutes. The stage of excitement is markedly diminished and generally absent. The quantity of ether is reduced from that used by the cone method to about one-half. Asphyxiation, cyanosis, stertorous breathing, swallowing of the tongue, and vomiting during etherization are of rare occurrence. We are firmly convinced that this open, economical, and safe method of etherization will be the accepted method of the future. J. B. Murphy, in his recent year book, says that "Ether should never be used upon the cone." While this method is simple, it still must be used with certain rules, and I find that these are not generally appreciated.

If I may be permitted, I will repeat the technique which I quoted from the paper of Miss Alice McGaw of Rochester, Minn. She says: "A thick pad of moistened cotton is placed over the eyes to protect them from the anesthetic. The inhaler used is the Esmarch mask with two thicknesses of stockinet. The mask should be boiled and the stockinet changed after each patient. Ether is given by the drop method from the original can, provided with a notched cork and a bit of gauze protruding to direct the drops, and as slowly and carefully and with as much air as though you were using chloroform, continuing until the patient's face is flushed. You then add a few layers of surgeon's gauze to the stockinet covering and give ether a trifle faster, until the patient is asleep. We then remove the gauze and continue with the same covering as at the start." She adds: "After complete narcosis, it is surprising how little ether is required to keep the patient in a perfect state of surgical anesthesia. Cutaneous sensibility is tested by pinching the skin; the indications thus obtained are more reliable than those obtained by touching the conjunctiva, the latter being dangerous and often infecting the eye." In a series of 150 consecutive ether anesthesias by the drop method, administered by my associate, Dr. Orin R. Witter, the shortest time for establishing complete anesthesia was two minutes; the longest time was twenty-five minutes; average time, 7.86 minutes. The largest amount of ether used was 320 grams; the smallest amount used was 25 grams, and the average amount 106.30 grams. That some of our elderly patients with serious lesions recovered is as much due to Dr. Witter's skillful etherization as to the operator.

Elderly patients do not well tolerate shock. Every means should be taken to prevent its occurrence.

G. W. Crile and W. E. Lower, in an article in the *Journal of the American Medical Association*, June 17, 1905, give notes on 5,800 cases of major operations in discussing the prevention of shock and hemorrhage. They maintain that shock is chiefly the result of the effect on the vasomotor centers of different impulses, caused by trauma, exposure, etc. Among the certain necessary causes are given psychic excitation, hemorrhage, cold, acute and chronic infections, anemia, cachexia, collateral dis-

*Read before the Hartford County Medical Association, October, 1906.

eases, and age. So it behooves us in each case to study probable causes of shock and its prevention in so far as it is possible, avoiding trauma to the nerves and viscera, hemorrhage, exposure of body to cold, avoidance of operations during acute infections where it is possible and where the hemoglobin indicates a very marked anemia.

The treatment of shock in these aged patients is important. If hemorrhage has been thoroughly controlled, remedies which raise blood pressure, such as adrenalin and aseptic ergot, are certainly indicated.

We still have faith in strychnine, although by some its usefulness is disputed. The infusion of physiological saline solution into the tissues by hypodermoclysis, and a method which we are now using in nearly all severe operations—slow introduction of moderate quantities of saline solution just within the anal sphincter, in conjunction with elevating the foot of the bed twelve inches—are both of great value. In extreme cases of depletion from either shock or hemorrhage, the direct transfusion of arterial blood into a vein of the patient is probably the most positive method of resuscitation at our command.

In referring to my surgical records, I find that in a series of 1,000 operations in general surgery I have operated upon 167 patients over 50 years of age, the average being 69 years. Conditions for which these patients were operated upon are as follows: Appendicitis, 16; benign tumor of breast, 1; carcinoma, of pelvis 1, of intestine 4, of stomach and pancreas 1, of stomach 3, of breast 7, of gall-bladder 1, of urinary bladder 1, of pancreas 1, of uterus 4, of prostate 10; epithelioma, of lip 2, of neck 1; deep abscess of cervical region, 1; melanosarcoma of foot, 1; sarcoma of scalp, 1; adenosarcoma, submaxillary region, 1; cholelithiasis, 13; cholangitis, 2; pyosalpinx, 1; diabetic gangrene, 2; accessory thyroid tumor, 1; general peritonitis, 6; enlarged prostate, 38; periurethral abscess, 1; hydrocele, 2; hernia, uncomplicated 8, strangulated 6; intestinal adhesion, 1; intestinal obstruction, 6; ovarian cyst, 3; psoas abscess, 1; plyoric obstruction, benign, 2; prolapse of bladder and uterus, 6; endometritis, 1; uterine polypus, 1; rectal fistula, 2; ischiorectal abscess, 2; senile gangrene, 4. Of these 167 cases, 65 were females, 102 males; 49 were between 50 and 60, 43 lived, 6 died, mortality 12.24 per cent.; 66 were between 60 and 70, 49 lived, 16 died, mortality 24.24 per cent.; 47 were between 70 and 80, 38 lived, 9 died, mortality 19.14 per cent.; 5 were between 80 and 90, none died.

There were 31 fatalities in the 165 cases, a mortality rate of 18.61 per cent. Fifty per cent. of this number were due to malignant diseases, and 30 per cent. to acute abdominal lesions; the remaining 20 per cent. were caused by diseases of the prostate, cholangitis, and diabetic gangrene. It will thus be seen that in clean, non-malignant, elective operations, the surgery of these aged people carries but a slight mortality. It is fair to say that a number of these operations, where malignant conditions were found, were not radical, but were for the purpose of drainage or were exploratory in character. Since compiling the above statistics my associate, Dr. George N. Bell, has operated upon a man ninety-one years of age for strangulated hernia, with primary union and recovery.

I will recite in detail but a few of these of the most advanced age:

Herniotomy for Strangulated Hernia.—E. S. Y., Unionville, Conn.; age 87; family history negative. Patient has had hernia for fifty-seven years, since 1849; several times it has been reduced with difficulty by various physicians. Present attack occurred twelve hours before my visit, following a drive of twenty-five miles. Dr. M. J. Morrisey employed taxis and applied poultices and ice bag. Patient is vomiting and is in much pain. Large scrotal hernia strangulated. Pulse gaseous. Patient's respiration rapid and wheezing. Moist, dry râles over chest. A decidedly poor surgical subject. Dr. Morrisey tried in vain for several hours to induce the family to permit operation. Consent was finally obtained. Operation at house, midnight. Ether, drop method. A large amount of intestine found in hernia; color dark, but gradually improved with hot saline packs. Patient's breathing became alarming during operation; laryngeal râles persisting after the operation. Rallied in one-half hour. Made uninterrupted recovery, with primary union.

Amputation of Breast for Carcinoma.—Mrs. H. H., Hartford, Conn.; age 87; family history negative. Has enjoyed good health until two years ago, when she discovered a tumor of the left breast involving nipple. The condition was kept from the family until the odor from discharge attracted attention. Tumor size of large grape fruit, indurated edges, sloughing and discharging at three points. The patient was anxious for operation, let the result be what it might; various members of the family, with one exception, objected strenuously. A distinguished surgeon in Chicago, who was consulted, wrote that it would be folly to amputate a breast at 87, as the patient's life would be shortened. This message came on the day that had been appointed for operation, and its performance was postponed some weeks. After writing the surgeon that the tumor was movable and I felt the operation was justifiable, he and the objecting members of the family consented. Ether was given by the drop method; the operation rapidly performed, the axilla not being entered. The wound was closed and healed by primary union. The patient enjoyed complete immunity from the pain, odor, and discharge. She died painlessly some months later from apoplexy.

Carcinoma of Breast.—Mrs. S., Terryville, Conn.; age 78; family history negative. Has been a hard-working woman of spare habit, but fairly well nourished until two years ago, when she noticed a small lump growing in right breast. Has had irregular heart action, and now has dilatation with mitral regurgitation, and has been considered at the hospital, where she applied for operation, to be an unsafe subject for an anesthetic. Operation under cocaine. Breast amputated. Primary union not attempted. Granulations gradually filled in, covering the surface, and the patient wrote from Terryville three years later that she had enjoyed fairly good health, but was then suffering from a recurrence.

Cholecystostomy for Cholelithiasis.—Mrs. E. B., West Hartford, Conn.; widow; age 82; family history negative. Was married and had several children between 20 and 35, since which time has been a domestic in one family. For past two years has suffered attacks of severe epigastric pain, accompanied by vomiting. During past three weeks has had three severe attacks. Patient now incapacitated; confined to bed. Slightly jaundiced. Marked tenderness over gall-bladder region. Operation, Hartford Hospital. Ether anesthesia. Gall-bladder found much enlarged; a number of fine cinder stones removed; one large stone obstructing cystic duct. Usual tube drainage. Scarcely any shock. No vomiting. No distention. Tube came out on sixth day. Patient sat up on eighth day. Made uneventful

ful recovery, and at once resumed her duties. This operation was performed two years ago. Patient is living and in good health.

Cholecystostomy for Cholelithiasis Following a Long Illness of Pneumonia.—Mrs. J. D. Y., Hartford, Conn.; age 72; mother and two sisters have suffered from gallstones. Health good until six months prior to present attack, when she suffered from asthma and bronchitis, with cardiac palpitation. Three months later suffered acute attack of bronchial pneumonia. Remained in typhoid state for several days. Rapid and audible respirations. Heart irregular and very frequent. Recovered slowly, with several relapses. Had been convalescent three weeks when she was seized with acute epigastric distress and vomiting. Pain was not relieved by vomiting. Forty-eight hours later pain and tenderness localized over gall-bladder region. P. 120; T. 103 1-2°. Drs. Porter, McKnight, and Abrams agreed with me that cholecystostomy was imperative. Husband objected on account of her age and feeble condition. Operation postponed for this reason twenty-four hours. Realizing that his wife was growing steadily worse, the husband consented. Operation at night. Gall-bladder contained quantity of pus and 34 large, irregular-shaped, sharp-pointed gallstones. Gall-bladder perforated by one of these stones, pus exuding into abdominal cavity. Gall-bladder drained by tube; abdominal cavity drained by gauze. Pulse and temperature steadily fell following operation. Vomiting ceased. With exception of attacks of cardiac weakness and distress, patient's recovery was uneventful.

Suppurative Appendicitis.—B. R., Hartford, Conn.; age 79; male; German; family history negative. Although in feeble health, had been able to be about until two weeks before entrance to hospital, March 2, 1902. Condition at this time was one of marked infection. T. 102°; P. 110, feeble and irregular. Patient vomiting, constipated, and complaining of pain in abdomen, which had existed for ten days. Physical examination revealed dilated, weak heart; subcrepitant râles at base of both lungs. Abdomen distended; tender at McBurney point, where a small tumor was palpable. Operation under cocaine anesthesia. Appendical abscess opened. Wick and gauze drainage. Prompt recovery.

Among this series of cases have occurred many agreeable surprises. In cases where age was coupled with crippled organs, arteriosclerosis, and a long history of progressive debility and emaciation, we have seen patients recover following operations, and we have been more than rewarded for the responsibility and the hazard we have taken. Truly, this cannot always be thus, and we must expect from the very nature of these cases to have some fatalities.

Among the commoner conditions occurring in the aged, calling for prompt surgical relief, may be mentioned strangulated hernia, intestinal obstruction from various causes, inflammatory and perforative lesions in the abdominal cavity, including the gall-bladder and the appendix; gangrenous extremities, retention of urine and sepsis of the urinary tract due to enlarged prostate.

The conditions calling for more deliberate surgical intervention are cataract, benign growths, hydrocele, varicocele and testis, prolapse of uterus and vaginal walls, and malignant neoplasms, and in the latter our results are even better than in younger subjects, because of the diminished activity of the lymphatic system and the lessened likelihood of metastasis and recurrence.

Enough has been said, I believe, to establish the propriety of surgical interference in emergencies which threaten life, and in conditions which destroy the peace and comfort in the elderly.

It is certainly our duty as physicians and surgeons to exercise as keen an interest in this class of patients as in those of younger years. We must remember that these patients are flesh and blood, entirely capable of suffering pain, and often most grateful for relief. Because they are old we must not consider that it is time for them to die. We should endeavor to prolong life, and prolong it in comfort. These aged patients are dear to some one, and their lives may still be of great value.

CORRECTION OF FAULTY FASHIONS IN DRESS AN IMPORTANT FACTOR IN THE TREATMENT OF DISEASES OF WOMEN.*

By WILLIAM EDWARDS FITCH, M.D.,

NEW YORK.

MEMBER OF THE AMERICAN MEDICAL EDITORS' ASSOCIATION; OF THE WEST SIDE CLINICAL SOCIETY; CLINICAL SOCIETY OF THE PRESBYTERIAN HOSPITAL; LECTURER ON SURGERY, FORDHAM UNIVERSITY SCHOOL OF MEDICINE; ATTENDING SURGEON ST. LUKE'S HOSPITAL DISPENSARY; ASSISTANT ATTENDING GYNECOLOGIST PRESBYTERIAN HOSPITAL DISPENSARY; ATTENDING PHYSICIAN VANDERBILT CLINIC COLLEGE OF PHYSICIANS AND SURGEONS.

"Seest thou not what a deformed thief this fashion is?"

When I was requested by the chairman of your program committee to prepare a paper of more or less universal interest to the general practitioner, I was at a loss to answer him, and asked for time. After much thoughtful consideration I became convinced that the subject of "tight lacing" was of special interest to the physician, as well as to the gynecologist, while to womankind it is of momentous importance; and my excuse for bringing this subject before you is the absolute necessity for seriously considering the subject of tight lacing as it exists to-day in all civilized countries.

Believing implicitly in the truth and earnestness of the views enunciated in this paper, I feel no degree of trepidation in condemning tight lacing, and ask your thoughtful consideration of the subject as philanthropists, humanitarians, and physicians. I fear that in the mad rush for scientific research we have, as physicians, overlooked the importance of this subject as an etiological factor in diseases of the female organs of generation. There is no one subject to which more importance should be given by the profession, and I shall try faithfully to point out in a practical manner the baneful effects of tight lacing, both as a factor in the etiology of disease and as an impediment to normal development of the uterine organs, which offers the greatest hindrance to disease, and at the same time to contrast the well-developed conditions and freedom from pelvic disorders in those who do not practice tight lacing, with frail constitutions, barrenness, and various uterine disorders found in those who wear the corset tight. I wish it understood, in the beginning, that tight lacing is not confined only to those who wear the corset, since the clothing may be worn so tight as to do practically the same harm, though to a less degree by gradual compression.

Before discussing this subject in detail, it might be well briefly to review the anatomy of the female pelvis, so that you may better comprehend the idea intended to be conveyed in this paper.

The female pelvis consists of a solid, unyielding structure of bones with a false pelvis representing

*Read before the West Side Clinical Society.

a truncated cone, the base looking upward, and slightly flattened on its anterior; the external and internal oblique, transversalis, pyramidalis, and rectus muscles, with sheaths and tendons combining, form the lateral and anterior walls of a cylinder continuous with the last named structure. The spinal column lined with the quadratus lumborum muscles form the posterior wall.

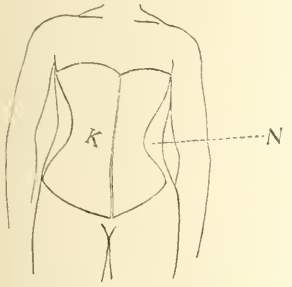

FIG. 1. K—Girl in the ordinary corset. N—Same girl without corset; normal waist line. Note comparisons.

Inclosed within this cylindrical body—pelvis and abdomen from diaphragm downward—are the various abdominal and pelvic organs, all readily and easily displaced by pressure.

Among these we find the uterus, which remains undeveloped and in an infantile state until near the approach of puberty, when it develops rapidly and continues to increase in size, proportionately to the rest of the body, until the normal size is reached, which is usually between the sixteenth and twentieth year. The virgin uterus is about two and one-half inches long; its width, at about the level of the Fallopian tubes, nearly one and three-quarter inches, and its weight about twelve drams. It is suspended in the pelvis by ligaments amounting to little less than folds of peritoneum. The Fallopian tubes and ovaries, with feeble supports, spread out on the right and left of the uterus in connection with the broad ligaments almost at right angles.

The ovaries, formed from the Wolffian bodies, rapidly begin to develop at the age of twelve, when a new era sets in, marked by maturation and periodical rupture of the Graafian follicles just before and after menstruation, and the remaining parts of the organs of generation rapidly increase in size.

FIG. 2.—Girl bending forward at work, showing how "tight lacing" increases abdominal pressure and depresses the pelvic organs.

In at least 85 per cent. of girls the generative organs develop between the twelfth and sixteenth years. It must not be overlooked that the uterus and appendages are covered almost entirely by peritoneum, which is very susceptible to injury, even from the slightest causes; that the construction of vessels supplying blood is of such a nature as to favor either anemia or congestion, proportionate to the degree of compression exerted. The free mobility of the uterus and appendages and the increased supply of blood the parts are receiving or should receive, enable us to more clearly understand the effects of pressure on an organ requiring rest and freedom during the period of development.

It is at or about this period, or more frequently earlier, that the young girl is allowed to commence wearing corsets, and she is not always given proper instructions as to the degree of constriction that should be permitted.

"Either thou are most ignorant by age or wert born a fool."

"Nature stood with stupid eyes,
And gaping mouth which testified surprise."

The law of growth in the human body is one which has not always been considered in relation to development of girls. The energies of the body rise and fall in each individual with a certain rhythm. Each swell of the physical growth is designed to bring about certain morphological and functional conditions, and when these conditions are not secured at the time Nature is accustomed to bring them about, or their maturation and development are interfered with by faulty fashions in dress, there is a possibility of their not being completed and perfected in subsequent years. The maturity of the sexual apparatus and its function in the girl must be accomplished at that stage of development known as puberty. It is, of all periods in the life of woman, the most important, for her future health, both physical and mental, depends upon its completion and perfection. All the care

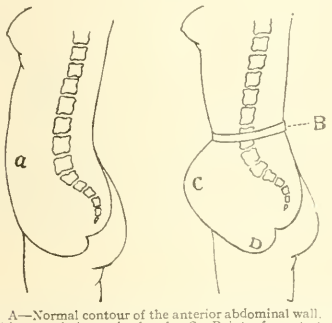

FIG. 3. A—Normal contour of the anterior abdominal wall. B—Same patient with constricting waist band. C—Point of greatest protrusion. D—Pelvic floor bulged down from waist constriction (after Gallant).

and all the intelligence that it is possible for mothers and physicians to bestow upon her should be given at this time. Not only motherhood and subsequent health, but sanity and lifelong happiness depend upon the perfect development of the female organs of generation. It does not seem unreasonable, therefore, that the foolish fashion and evil custom of wearing tight corsets should be tabooed.

The corset offered in the shops is so constructed that, when worn, it exerts its greatest constriction, pressure, from an inch or so above the brim of the pelvis downward, constricting the abdominal walls, the lower part of the thorax, and pushing inward the costal cartilages, often causing the seventh and eighth ribs to overlap. (Fig. 1.) The greatest point of constriction and compression is at the waist line, in the immediate neighborhood of the stomach, which, when distended, as after a hearty meal, produces the "hour-glass" stomach, often observed in this class of patients.

Tight lacing forces and crowds the small intestines with accompanying mesentery and colon into the pelvis, filling Douglas' anterior cul-de-sac; if the rectum is loaded with feces and the bladder empty anteversion of the uterus follows; if the bladder is distended, and the rectum empty, retroversion results, displacing the intestines into the posterior cul-de-sac. In most of these cases, where

the compression is great enough to interfere with and retard the normal peristaltic action of the intestines, constipation is also produced.

We no longer doubt that compression of any part or organ interferes with physiological growth and function; therefore, all women who wear tight corsets and constricting waist-bands, breathe with a well-marked sternal movement, which is unnatural, since Nature intended woman to breathe like man, abdominally. Women when asleep breathe like men, and all animals, male and female, breathe alike, abdominally. Mays has shown that Indian girls breathe like men, and Kellogg has confirmed this observation. Among several Indian tribes, Chinese women, agricultural women, English pit-brow lassies, and civilized women who wear their clothing loose at the waist or suspended from the shoulder, all show the same type of abdominal breathing, and the flimsy argument that chest breathing is normal to women, because it is necessary during gestation, goes to the wind when it is shown that even in the last months of pregnancy abdominal respiratory movements predominate over thoracic movements. The most active respiratory organ, that muscle of respiration, the diaphragm, adapts itself most beautifully to circumstances, so that, when from tight lacing the abdomen is constricted, the type of breathing becomes thoracic; when pressure is relieved it again changes to the abdominal type.

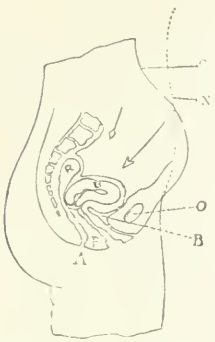

FIG. 4. C—Corset line. N—Normal outline. U—Uterus forced down by corset, producing anti-flexion. O—Os pubis. B—Empty bladder. R—Loaded rectum. P—Perineal body. A—Anus.

The Egyptians, who were foremost in the promotion of civilization, education, and art, while allowing variations in luxuries, were the first to formulate legal barriers against the introduction of "any new ideas" of fashion in articles of dress tending to constrict the waist, or in any way to attempt to modify the true teachings of Nature.

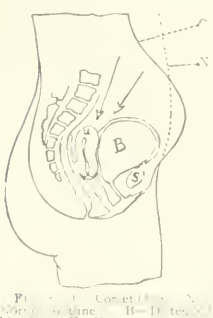

FIG. [illegible] C—Corset line. N—Normal outline. B—Distended bladder. U—Uterus retroverted from [illegible] lying. S—Symphysis pubis.

Do tight lacing and faulty dress interfere with normal abdominal respiration? The reasons for an affirmative answer are based on recent experimental researches, by which certain facts seem well established that heretofore have largely been matters of speculation, opinion, or prejudice; therefore, we conclude as follows: (1) Normal breathing in woman is like that of man—abdominal; tight lacing changes the type to costal. (2) The pelvic organs normally make a considerable excursion with each respiration; tight lacing in the ambulatory position prevents this motion almost entirely. (3) Sitting or leaning forward lessens intraabdominal pressure; tight lacing in these positions greatly increases intraabdominal pressure (Fig. 2); (4) Tight lacing displaces the uterus downward from 2 to 3 inches; (5) The pelvic floor is bulged downward by tight lacing from 2½ to 3 inches, and the circulation is rendered sluggish. (6) Undue constriction of the waist from corsets is a constant impediment to free indoor exercise and outdoor gymnastics is hampered. (Fig. 3.) (7) It has been shown that a loose-fitting corset diminishes chest capacity one-fifth, and a tight-fitting corset tends to atrophy of the abdominal muscle and accumulation of fat. (8) With each movement of the diaphragm the structures of the pelvic floor with the uterus and its adnexa are carried downward from 1 to 3 inches and up again; in the case of women who have worn loose clothing about the waist.

Alternating pressure and relaxation accelerates the free flow of blood through the large venous plexuses and lymphatics; alternating traction and relaxation tend to develop uterine ligaments and their peritoneal investment, and give tone to the muscular pelvic floor; alternate stretching and slackening tone up elastic supports. With each full inspiration the descent of the diaphragm increases abdominal pressure and lessens that in the chest; blood is forced out of the portal and pelvic veins and sucked up above the diaphragm; therefore, it is plain to the critical observer that any form of dress that cripples the free excursions of the diaphragm impedes the pelvic circulation. The blood flow of the uterine organs is seriously hindered in another way. The valveless ovarian veins empty in the area of greatest corset pressure, which causes a damming back of a long column of blood.

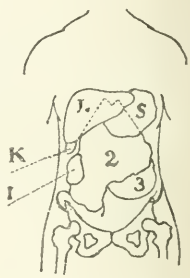

FIG. 6. K, L, S—Kidney, liver and stomach in normal position. 1, 2, 3—Same organs displaced by tight lacing.

When a constricting corset is worn, little or no motion can occur, because all the structures in the true pelvis are carried downward by constant pressure and crammed into the cylindrical cone-pelvis so tightly as entirely to impede movement.

Kellogg and others have demonstrated that pressure from a tight corset, or from a loose corset with the wearer stooping over or bending forward, bulges the pelvic floor downward to the utmost limit of its capacity, and the uterus is correspondingly forced to descend. This constant pressure for hours keeps the uterine supports tense and stretched for many hours daily, while exertion or stooping overstrains these taut structures still further.

Africans, Indians, Eskimos, and all other nations who wear loose-fitting clothing, are almost entirely free from pelvic disease. It is in this class of women that we find the most natural and perfect pregnancy, the easiest and almost painless deliveries, and the most rapid and perfectly satisfactory puerperium. Any physician who has practised medicine in the rural districts for the well-developed and healthy country woman, and later in the city for the dainty, delicate, badly nourished, and poorly developed, where tight lacing and other foolish fashions are practically universal, will soon be convinced that there is an explanation for the frequency of female ills and frailty in the latter, as compared with the freshness, vim, and vigor, and fine physique of the former.

To any clear-minded, thinking physician there can be no doubt of the claim that 75 per cent. of the

women who habitually practise tight lacing to any considerable extent, suffer from maldevelopment of the uterine organs, especially if the corset is worn at that period of life when uterine development conduces to diseased conditions, and practically renders the normal physiological functions of organs incomplete and painful; nor will it be longer doubted by the close observer of passing events. Uterine displacement, that subject about which so much has been written during the recent past, and the treatment of which has been so varied that "falling of the womb" is prevalent in the minds of so many women and a "hobby" for such a large number of doctors in the main, may be laid to the corset.

In no forms of mammalia, other than womankind of the civilized races, do we find uterine displacement or diseased conditions of the generative organs. Why is this? Tight lacing displaces the uterine organs and appendages and maldevelopment is the result. In anteflexion, which is often accompanied by inflammation of the uterosacral ligaments, the downward traction on the tender ligaments is especially dangerous; moreover, the increased pressure from above flexes the uterus still further when the bladder is empty. (Fig. 4). Dickinson relates a case of a robust dressmaker who consulted him, measuring five inches less with corsets on, than over her undershirt with corsets off. The cervix and fundus met, so extensive was the bend; without other treatment than removal of the corsets the uterus assumed its normal position in three weeks. In descensus of any degree the ordinary corset should not be worn.

In retroversion the pressure is exerted on the anterior surface of the uterus, forcing the fundus backward. Indeed, whenever an overdistended bladder tilts the organ backward, abdominal pressure increases the displacement. (Fig. 5.) Kellogg and others have shown by autopsy that the abdominal organs are displaced by corset wearing. The liver has often been found pushed downward, even to the iliac crest. One or both kidneys, in 30 out of 100 cases examined, were found abnormally low. (Fig. 6.)

Maldevelopment of the uterus and appendages affects menstruation in various ways. Amenorrhea is frequently the result of a poorly developed mucosa and uterine adnexa, together with faulty-developed ovaries—a condition which, if neglected, often leads to atrophy; or one may find congestion-menorrhagia with long-continued, profuse flows. Dysmenorrhea is a condition mainly due to maldevelopment of both uterus and appendages, the nervous system, and also to the imperfect development of the muscular and cellular tissue entering into their makeup, rendering them inadequate to their physiological requirements.

Physiologists tell us that there are in the uterus embryonic cells which remain throughout life; they are the cause of epithelioma of the cervix, and the cervix in 98 per cent. of cases is the seat of uterine cancer, local irritation and ulceration being the exciting causes. Tight lacing by producing malposition forces the os downward against the floor of the vagina, causing inflammation, irritation, and eventually ulceration. A prominent author says: "Up to puberty the mortality for carcinoma is the same; afterward the relative proportion of female to male deaths gradually rises till it attains its maximum at about the sixtieth year. Cancer of the uterus is a rare disease among Indian women, yet occurring with great frequency in all civilized countries, must have its explanation in some custom peculiar to such civilization."

Miscarriages, lacerated cervix, weak and inefficient contractions of the uterus in labor, protracted puerperium, the result of subinvolution, may often find their true explanation, directly or indirectly, in maldevelopment. The increased frequency of endometritis, hyperplasia, erosion, stenosis, sterility, and atresia of the cervix and os, must be largely due to this cause. A large number of the parauterine cysts, as well as papillomatous cysts of the hilum, parovarian cysts of the broad ligaments, have their origin in these unobliterated ducts and the remains of the Wolffian bodies. Maldevelopment is surely accountable for this condition of affairs. Fibroid and other tumors of the uterus have their etiology in maldevelopment of the organs of generation.

During the past few decades the Germans, who have always been early and earnest workers in new fields, have been busy inventing new bandages, supports, and corsets for displaced organs. Israel of Berlin, in a comparatively recent monograph, describes a waist that acts by not interfering with the normal motions of the body, nor having any pads for making direct pressure over any of the abdominal organs, or the organs of generation. It is an

Fig. 7. The proper way of adjusting the corset (after Gallant).

apparatus with triangular air cushions made to fit just above Poupart's ligament and the iliac crests, and held in place by elastic bandages reinforced by braces and stays.

A few years ago, Gallant of New York published some original ideas on a new straight-front corset as an ideal orthopedic kidney support. He believes that the weight of the clothing and compression at the waist line at and after puberty have an important effect on girls in producing movable kidneys. He recalls fifty cases where he made careful measurements and found abnormalities in the length of the trunk, as shown by the distance between the suprasternal notch and upper border of the symphysis pubis, and deviation from the normal relation between the circumference of the waist and of the hips at the trochanters. There was a hollowing of the epigastrium and bulging of the hypogastrium. A respiratory rise and fall of the greater curvature of the stomach was observed in thin-walled subjects.

Displacement occurred frequently after childbirth, which could have been remedied by a firm abdominal binder and exercises while in bed. Prolapse of the colon and stomach was generally associated with that of the kidney. These conditions were not remedied by operation. According to Gallant, a properly shaped corset, put on before rising, in a semiopisthotonous position, makes the patient comfortable and prevents complications.

Another investigator of this city, working along

independent lines, has perfected the straight-front corset—a specially designed abdominal corset that meets the demand of physicians for one that will successfully support displaced organs. This corset is built on lines different from those of other corsets, and when perfectly fitted lowers the waist line in front, gives perfect freedom of movement to the entire chest cavity, allows deep breathing, and at the same time gives direct pressure and support from below upward and backward throughout the lower abdominal region, which not only reduces a large abdomen, but holds in place all prolapsed viscera. There is no constriction at the waist line nor above; all the compression is across the hips and lower abdomen, which is lifted upward and backward, leaving the chest free, allowing deep breathing, permitting chest expansion, and favoring an erect carriage. This corset is made with a long graceful straight front which covers the abdomen to the os pubis, at the same time adding support to the diaphragm, instead of breaking it down, as do some corsets. The waist line runs below the short ribs, which lengthens the waist, producing graceful lines without compression, encouraging deep respiratory movements with the effect of enlarging the bust measure and throwing the chest forward.

Rigidity, instead of flexibility, is characteristic of most corsets, but the one here described is flexible and elastic, and yields to every movement of the body, leaving the thoracic, abdominal, and pelvic organs in their normal and natural position of unrestricted freedom. A woman feels no need of loosening this corset, nor feels the need, when it is removed, of taking a deep breath. On the other hand, most women who practise tight lacing complain of pain on removing their corsets. This pain is caused by the displaced organs attempting to assume their normal position. This corset reduces a large abdomen, holds in place all prolapsed viscera, and at the same time preserves all the style and elegance of figure of the ultrafashionable. As a surgical corset, it is indicated in floating kidney, enteroptosis, gastroptosis, dilatation of the stomach, and for supporting the abdomen after laparotomy and parturition.

The Lafayette, 320 Manhattan Avenue

THE W. GILL WYLIE APPENDIX OPERATION.

By JOHN H. RICHARDS, M.D.,

NEW YORK.

ASSISTANT IN CHEMICAL PATHOLOGY, CORNELL UNIVERSITY, MEDICAL SCHOOL.

That in these days of advanced surgery a man should declare that he is now doing, and has been doing for the last five years, an operation for the removal of the appendix, the technique of which is generally unknown to surgeons, is indeed strange. However, such is the case. I refer to the method employed by W. Gill Wylie. Dr. Wylie has never written on the subject, so none but his assistants are acquainted with his operation, and I have never heard of anyone who employs the same technique, excepting those few to whom Dr. Wylie has shown the operation. The remarkable results obtained by this operation sufficiently justify, I think, the writing of this paper.

Before describing in detail the modus operandi, I will briefly state the class of cases for which this operative technique is adapted: (1) All chronic cases; (2) all acute cases before rupture; (3) all cases of open appendix. By "open appendix" I refer to those cases in which there is free opening or drainage from the appendix into the cecum. There may be catarrhal or ulcerative inflammation present, but on account of the anomalous anatomical conditions in these cases, the secretions are drained into the cecum; while in cases of ordinary anatomical structure there is a twist or constriction at the mouth of the appendix which prevents this drainage and aids very materially in perforation when such an appendix is inflamed. Of all noninflamed appendices examined, from 92 per cent. to 97 per cent. show this constriction (Cunningham). In spite of the large percentage of this type found in noninflamed appendices, Dr. Wylie's observations made from cases on the operating table have led him to the conclusion that most cases of inflamed appendices are of the open type. This type is sometimes called the persistent fetal type. The reason given for this predisposition of the open appendix to inflammation is that the funnel-like mouth of such an appendix favors the entrance of fecal matter, which of course favors inflammation, but at the same time permits of drainage into the cecum. Such appendices, although prone to inflammation, seldom perforate during the first attack on account of the drainage, but this drainage may become occluded in a second or third attack on account of the cicatricial stenosis formed by the healing of the ulcers in the appendix.

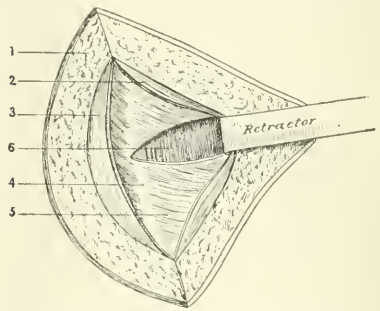

Fig. 1.—1, Subcutaneous fat; 2, aponeurosis, inner flap; 3, aponeurosis, outer flap; 4, linea semilunaris; 5, anterior sheath of rectus; 6 rectus muscle exposed.

These appendices with such stenoses give the same symptoms clinically as do those with the normal constriction, because the same tendency to gangrenous inflammation is present.

Detail of the Operation.—1. Skin incision. This is begun a little to the right of the linea semilunaris and extended obliquely downward and inward, so that the lower end of the incision just crosses the linea. The incision is made two or three inches long, or longer in fat subjects, so that during the search for the appendix the tissues are not macerated by the knuckles, and the different layers thereby obscured to such an extent that homologous apposition cannot be secured. The objection raised to the long incision is that it leaves such a long scar. This objection is not warranted, for in hundreds of cases sutured in the manner I shall describe later, the scar is only a fine line perfectly movable and found only on close inspection. While if it is not sewed up in this way, and one cannot do it if the tissues have been roughly handled, the scar invariably spreads and dimples. This is certainly a point in favor of the long incision.

2. The incision of the aponeurosis of the external oblique is made a little shorter than the skin incision and in the direction of its fibers. This incision will thus follow the line of the skin incision.

The inner flap of the aponeurosis is then retracted toward the median line, thus exposing the fibers of the internal oblique muscle, the linea semilunaris, and the anterior sheath of the rectus. Sometimes the aponeurosis is adherent to the anterior sheath of the rectus, but this can be separated usually with the back of a knife. Having thus exposed the rectus for about an inch toward the median line, one can readily see, as Dr. Wylie has taught for twenty years, that the transverse strength of the abdominal wall is toward the linea alba, and that this strength extends along the fasciæ in a transverse direction, the sheath of the rectus acting as the tendon of the oblique muscles of the abdominal wall with the linea alba as its insertion. The rectus muscles give longitudinal, but no transverse strength. It is for these reasons that, if an incision is to be made through the sheath of the rectus, it should be made in a transverse direction, so that when the abdominal muscles contract after operation the wound in the sheath will not be found to spread open.

3. Incision of the anterior layer of the sheath of the rectus. As illustrated in Fig. 1, this layer is cut in the direction of its fibers for about one and one-third inches, beginning at the linea semilunaris and extending toward the linea alba, thereby exposing the rectus muscle. A small retractor about

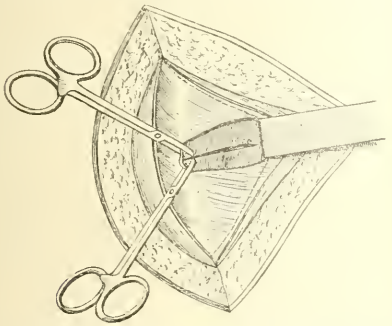

FIG. 2.—As indicated by the dotted line, the rectus is pulled inward, thereby exposing the posterior sheath of the rectus; this is then incised as indicated.

one inch wide is then used to pull the rectus toward the median line. Then two forceps (Fig. 2) are placed at the linea semilunaris, and the posterior layer of the sheath of the rectus with the peritoneum is cut parallel to the incision of the anterior sheath. This incision is made about one inch long, or long enough to admit the index finger of the left hand comfortably. Dr. Wylie has demonstrated during operation, by allowing the patient to come out of ether partially, that a contraction of the oblique abdominal muscles, as in vomiting, will approximate the cut edges of the sheath, while a cut made in the opposite direction (the one made in Kammerer's and Deaver's operations) will spread open during such a contraction. Also the contraction of the recti muscles produces the same effect, instead of the opposite, as is generally supposed. This can be explained by the fact that the sheath is adherent at the lineæ transversæ only, so any shortening of the recti muscles will tend to produce a relaxation of the sheath between the lineæ transversæ, and thus any longitudinal cut will spread open and any transverse cut will tend to close.

4. Search for the appendix. Dr. Wylie uses the index finger of the left hand and palpates first the brim of the true pelvis; then, with a sweep upwards and outwards on the posterior abdominal wall, he finds the appendix, and delivers it with a small sponge holding forceps. This forceps is made with a small end and a joint as far from its end as Dr. Wylie's index finger is long, and so weak that when brought to the last catch the bite is not strong enough to damage the intestine. There is seldom any trouble in delivering the appendix.

5. Removal of the appendix. The mesentery of the appendix is ligated with catgut and cut, section ligation being used if necessary. A purse-string suture of fine catgut is then placed about the end of the cecum, far enough away from the base of the appendix to permit its being turned in. This suture is not tied until the appendix has been cut away. Next the appendix is tied near its base with small catgut. Then the appendix is crushed distally to this tie by an artery clamp, crushing out everything but the serosa. Now the appendix is amputated just distally to this tie in the area crushed. The stump is carbolized and turned in while the purse-string suture is tied. By this means the end of the cecum is completely covered by peritoneum, and any abscess that may form in the stump of the appendix will break into the cecum and drain itself. The omentum is then brought down into its normal position and the abdominal wall sewed up as follows:

6. Suture of the abdominal wall. Dr. Wylie says that the most important procedure in the suture of the abdominal wall is the perfect adjustment of the fasciæ in homologous apposition. He uses fine catgut throughout. The following layers are sewed: (1) Peritoneum. (2) Fasciæ extending down from the fold of Douglas' posterior to the rectus muscle. (3) Anterior layer of the sheath of the rectus. (4) Thin areolar tissue over sheath; this is done so that the aponeurosis will slide upon the sheath and not become adherent to it. (5) Aponeurosis of the external oblique. (6) Areolar tissue. (7) The deep and superficial layers of fasciæ, which form what he calls the "tics" of the layer of fat. These tics are always found on close inspection running somewhat irregularly through the fat, and should be sewed up to catch the edges of the two mattresses of fat formed by these two tics. This procedure prevents dimpling and spreading of the wound. (8) Skin.

Advantages of the Operation.—(1) Not a muscle fiber is cut. (2) There is no danger of hernia. (3) From a mechanical point of view it does not weaken the abdominal wall. (4) From an artistic point of view the scar left is with difficulty to be found. (5) The peritoneum is opened for only one inch.

Disadvantages of the Operation.—(1) The incision cannot be extensively enlarged readily if such is needed. It can be enlarged in two ways: (*a*) Extend incision into the fibers of the external oblique, which is done in the few cases which require drainage. (*b*) Make Kammerer's incision in the sheath and sew up the transverse incision. I have never seen Dr. Wylie enlarge his original incision. In one case in which the appendix was in the left iliac fossa he sewed up his original incision and made a second in the median line. This latter incision he prefers in all cases of general peritonitis from rupture of the appendix.

2. The search for the appendix requires a keen sense of touch.

215 WEST FORTY-THIRD STREET

Medical Knowledge of Frederick the Great.—A book has recently been published in Berlin entitled "Correspondence of Frederick the Great with Physicians." The published documents show that the king possessed deep knowledge of the medical science of his day. He founded the Charité Hospital.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE

New York, October 19, 1907.

THE POSSIBLE DANGERS OF SALINE INFUSIONS.

It has long been recognized that the introduction into the blood-vessels of considerable quantities of ostensibly "physiological" salt solution is by no means the indifferent procedure it was at first considered. Edema of the lungs, watery diarrhea, effusions into the serous cavities, and collapse have been known to follow the ill-advised resort to what, when properly used, may be a life-saving measure, and it is evident that the indications for and limitations of the procedure, as well as its dangers, have not yet reached the precise state desirable from both the theoretical and practical standpoints. It is possible that if the practice of infusion, instead of dating back to a score or more of years ago, before the development of the modern lore of osmotic pressures and of the laws of solutions and interchange of ions, were a more recent suggestion, more caution would have been exercised in its application, and its use would be restricted to a more clear-cut set of conditions.

Rössle, writing in the *Berliner klinische Wochenschrift* of September 16, 1907, notes a condition of the heart muscle which he has found in a sufficient number of cases to enable him to determine with a reasonable degree of accuracy from the post-mortem appearances that an infusion has been given shortly before death. These consist in a macroscopic cloudy swelling of the muscle, together with poor contraction and a friable consistency, though no microscopic evidence of parenchymatous degeneration is to be discovered. He furthermore describes two cases in which he considers that the autopsy showed a directly injurious effect of the infusions given, in the one case for collapse during a forceps delivery, and in the other in conjunction with the removal of a large ovarian cyst. In these cases serous diarrhea and ascites respectively followed the infusions and numerous organs and tissues, including the kidneys, revealed edematous accumulations of fluid. While saline infusions are usually given only in cases of considerable gravity, and in which the clinical picture is a complicated one, so that the interpretation of post-mortem findings is very difficult, there is little doubt that greater caution than is usually exercised is desirable in formulating the indications for the procedure. It would appear to be unsuited for use purely as a cardiac stimulant, and to be not free from danger when the kidneys are incompetent, while observation of the fundamental rules in regard to accuracy in making the solution, and keeping it at the required temperature, slowness of flow into the vein, and administration of only small amounts at a time is absolutely necessary. *Post hoc ergo propter hoc* reasoning is always unsatisfactory, but it is probable that a careful analysis of the cases in which death has followed saline infusion would be highly instructive, and, perhaps, by pointing out some of its contraindications, would serve to enhance the value of a measure of approved merit.

AN INDICATION OF ADEQUATE NURSING.

Nothing so well indicates that an infant is thriving and is getting the proper food as an increase in its body weight. A decrease, on the other hand, while it may be due to various conditions, is in the majority of cases caused by improper nourishment, which in a nursing baby usually means an insufficient amount of food rather than food of poor quality. It therefore becomes a matter of great importance to decide whether the nursing is adequate, *i.e.* whether the child is getting enough food. The amount of milk ingested may be ascertained by weighing the infant carefully before and after each feeding during twenty-four hours.

Süsswein, writing in the *Archiv für Kinderheilkunde*, Vol. 40, Nos. 1-3, says he has recently studied the action of healthy and sick infants, both at easy running breasts and those which empty themselves with difficulty. The number of times a baby drew at a breast and the number of times it swallowed were carefully counted, the acts of swallowing most easily by placing the finger lightly upon the larynx. He found that a healthy infant put to an easily running breast drew from forty to ninety times in each of the first two to three minutes, each act of sucking being followed by an act of swallowing, while after the third minute there was only one act of swallowing to every two, three, or four of sucking. The infant seemed to draw more rapidly after the third minute, though in reality the average number of times it drew per minute was smaller than during the first few minutes of nursing, this being due to the fact that it rested now and then at this period. As the quantity of milk ingested depends on the number of times the infant swallows, it must become less and less after the third minute, in fact more than one-half of the meal is taken in the first five minutes. The children were weighed at various times during a meal, the average amount of milk ingested at each act of swallowing being six-tenths of a gram, and thus the total amount per feeding and during twenty-four hours could be calculated. When the same healthy infant was put to a breast which emptied itself with difficulty, the acts of sucking were less frequent from the start, and while each was at first followed by an act of swallowing the proportion of two to one and higher set in before three minutes were up, and the rests while drinking also set in earlier, the child thus getting less in a given time than from the easily running breast; in other words, it had to nurse much longer to get the same amount. In weak and premature infants the acts of sucking were still less frequent in the first few minutes, and while each was at first also followed by an act of swallowing, very soon two or more had to take place before an act of swallow-

ing set in; the rests during drinking also took place much earlier, the infants therefore usually did not get the necessary amount of food, even if they were put to the breast more frequently.

Süsswein thus approximated the amount of milk an infant ingested (confirming his results by also using the scales), and found the nursing to be adequate when the relation of the act of sucking to the act of swallowing was as one to one for the first three minutes and when at the same time more than half of the meal was ingested in the first five minutes. When the infant swallows seldom and rests early there is something wrong. This method, therefore, also enables one to determine the necessary length of the meal and the amount ingested at each; at the same time it is an aid in selecting a wet nurse. Though it is not as exact as weighing before and after each feeding, Süsswein thinks it is more practical.

VENEREAL "JACK."

Of the sailors annually entering this port and leaving it, 100,000 are estimated to be affected by venereal diseases. The number infected here and carrying their diseases to other ports is beyond computation. These factors in the increase of venereal diseases are not usually considered by writers on these ailments.

The Society of Sanitary and Moral Prophylaxis has shown that the essential need at present is in teaching the community the dangers of venereal diseases. It is, however, only the most exceptional sailor who can, especially after a long voyage, be brought to attend lectures or read pamphlets of any kind. He has stood a season of hardship, his pockets are comfortably filled, his ideas of morality are circumscribed, temptations are thrust upon him by liquor dealers and prostitutes. Small wonder that he has "a good time" while he is idle. The consequences are shown by the figures given above. When infected, as a result of his debauch, there is no institution which offers to relieve him and the community from the dangers thereof. If "Jack" has any money left he has recourse to the quacks, whose advertisements and runners are his only informants on the subject. There is, consequently, manifest need for an institution that will properly care for these disseminators of venereal diseases. The men admitted thereto because of their infections are in a receptive stage for that instruction which can lead them to avoid again becoming a menace to themselves, their families, and the countries to which their occupation takes them.

Dr. William T. Jenkins, for a number of years Health Officer of the Port, has had the best possible opportunities to study this ponderous menace to the entire civilized world. In an "Appeal to the Philanthropic" he sets forth the need of methodically protecting, especially our country, from the annual importation of at least 100,000 disseminators of venereal diseases. This he proposes to do primarily by the establishment of a public hospital avowedly for the purpose of treatment of the affections under consideration. The possibilities for good of such an institution are not discutible in brief consideration. Moreover, to the medical profession they are self-evident. In view of our deep-rooted Anglo-Saxon prejudice against at all recognizing the existence of the results of sexual immorality, Dr. Jenkins' self-set task is enormous. He counts, however, on the 130,000 physicians of the United States to give him moral support in convincing the public that every person, every house, every community is imperiled far more by venereal diseases than by all the other infections against which quarantine is now recognized as a public necessity.

THE NEW SCIENCE—EUGENICS.

Frequent reference is now made in current literature to the new science, eugenics, which is after all an old science, repopularized in the recent Robert Boyle lecture at Oxford by Prof. Karl Pearson. The inventor of the science, Mr. Francis Galton, defines it as "the study of a genesis under social control that may improve or impair the racial qualities of future generations either physically or mentally." The new science has manifestly a wide range of application. Such a range of investigation as is implied obviously includes problems of inheritance, environment, nurture, health and disease, vigor and impotence, intelligence and stupidity, conscientiousness and irresponsibility, clean living and license, and sanitation in its broadest sense. It thus touches at innumerable points the work of the medical man.

Prof. Pearson says that all sciences pass through three distinct stages of development. As phrased in a review of his lecture in a recent issue of the *British Medical Journal* of September 21, 1907, these may be stated as follows: "First, the ideological in which you evolve your camel from your inner consciousness. Second, the observational in which you study the form and habits of the real camel, and, third, the metrical in which you measure the camel and study its relation to other camels, and to the rest of nature. Eugenics had reached a certain stage of development when Plato first wrote his *Laws;* indeed, it was already passing from the first to the second stage, but it has been the last of the sciences to enter the third stage, and here its pilot is "biometrics."

The science of biometrics applies mathematical methods to various kinds of association which lack the absolute dependence of pure causation. It applies to biological data, in a general way, the same methods the actuary uses in calculating a life table. A typical emanation from a eugenics laboratory is that consisting of a recent study of data bearing on the degree to which some forms of intellectual ability may be regarded as hereditary. Thus two workers in the laboratory endowed by Mr. Galton have analyzed the Oxford examination records and the school lists of Harrow and Charterhouse. These studies show that "there is a relationship between the class obtained by a father and that of his son at Oxford, and also between the respective successes of brothers. It is further shown from the Harrow and Charterhouse returns that there is a relationship between the position in the school of brothers at the end of the same number of years from entry in each case. The values of the correlation coefficients are appreciably lower than those obtained for the inheritance of physical characters in man, and the authors discuss some of the possible reasons—for instance, the fact that even

skilfully conducted examinations are not ideal tests of ability, and cannot be compared in respect of accuracy with physical measurements. Still further, there have been collected between three hundred and four hundred pedigrees of tuberculous stock; four hundred family histories of insanity, four hundred descriptions of parentage and home environment of mentally defective children with as many more of normal children, the records of nearly four hundred noteworthy families with psychical and physical description and entries as to ailments and causes of death. The scope of the work of eugenics is thus indicated.

Now, it may seem a long reach from such work to the problems of clinical medicine, and the work thus far done may not seem to differ appreciably from that now carried on in so many ways for social betterment, but without doubt a mass of facts has been and is being collected from which the future may draw valuable conclusions. Does such work constitute a true science? A recent writer observes that we may be fairly sure that the new science will not be adopted into the hierarchy until its field is more sharply defined, its methods perfected, and its pretensions substantiated. He notes that the misfortune of such a science is that it attracts as its votaries men who are prone to slipshod thinking and haphazard generalization. Of these faults, medical science has already too many. Prof. Pearson declares that "not only the medical profession, but statesmen, disregard two great principles, the inheritance of variations and the correlation in heredity of unlike imperfections." If the influence of eugenics on medicine shall lead to more careful thinking and statement, and a greater realization of all the factors concerned in health and disease, its influence cannot but be most salutary. But physicians have already covered much of the ground seized upon by eugenics as virgin soil, although they have chosen their own definitions, which frequently differ from those employed by the new science devotees, and considered as something quite different, although they are practically the same. Sociology is, after all, but a department of biology, and the new workers seem to be but copyists of old methods.

The Mode of Infection in Pulmonary Tuberculosis.

The particular predisposition of the lung to tuberculous infection has always made it seem natural to assume that the infectious material gained access to the body through the respiratory tract. Those who share Koch's belief in the nonpathogenicity for man of the bovine bacillus, of course defend this position most warmly against the objections of v. Behring and his followers, who are of the opinion that the nonresisting intestinal mucosa of infancy is the most common portal of entry for the tubercle bacillus. This contention connotes a belief in the transmission of infection through milk, and consequently attributes widespread virulence for the human being to the bovine organism. Numerous observers have sought to throw light on the point at issue by experiments in which animals were caused to inhale tubercle bacilli or the organisms were introduced into the gastrointestinal tract. The results of this work have not been conclusive, however, and in fact are almost susceptible of being used as arguments in favor of either theory. Pfeiffer and Friedberger (*Deutsche medizinische Wochenschrift*, September 26, 1907) describe a series of such tests that appear to have been conducted with unusual care to avoid extraneous errors. As a result of these, out of twenty-eight guinea-pigs that received tubercle bacilli by stomach tube, twenty-one, when killed at the end of fifty days, exhibited no tuberculous lesions whatever, and only four had pulmonary lesions. Twenty-nine other guinea-pigs were caused to inhale the germs, and of these twenty-two manifested pulmonary tuberculosis. This discrepancy is the more striking as, owing to the manner in which the cultures were diluted, the inhalation animals could at most receive less than 3,000 bacilli, whereas the animals of the other series were given more than 3,000,000. This result is in harmony with Flügge's dictum that in guinea-pigs inhalation is a much more potent means of tuberculous infection than ingestion of the germs through the alimentary tract, and furnishes a cogent argument for those who hold that the practically important means of transmission in man is through inhalation and not through food.

The Tarsophalangeal Reflex.

Some years ago both Bechterew and Mendel called attention to a foot reflex which they averred would be found of use in distinguishing between organic and functional disease of the nervous system, but the sign does not seem to have attracted a great deal of attention as yet. It consists in the fact that when the dorsal surface of the foot is tapped with a percussion hammer over the third cuneiform or cuboid bone, dorsal extension of the second to the fifth toes is produced in normal persons, and in cases of functional nervous disease, whereas if organic lesions of the nervous system are present plantar flexion of the toes is caused. Recently two communications on this subject have appeared, one by Lissmann in the *Münchener medizinische Wochenschrift*, May 21, 1907, and the other by Meyer in the *Berliner klinische Wochenschrift*, August 26, 1907. One of the chief points of interest in connection with the reflex has been its relation to the Babinski reflex, and the former author states that he was not able in any case to elicit a positive Bechterew-Mendel reflex when the Babinski was negative. Meyer, however, reports ten cases in which the former reflex was constantly present, but the Babinski sign was either entirely absent or appeared only after the lapse of considerable time. It therefore appears that cases occur in which the Bechterew-Mendel reflex is present earlier than the Babinski, and that it accordingly has added diagnostic value in differentiating between organic and functional diseases, since it is a very early symptom of the former condition and forms a precursor of the Babinski sign, which is now so universally looked for.

Pemphigus Neonatorum.

As is well known, this not very uncommon disorder is a contagious disease affecting infants, usually between the fourth and ninth day after birth. Vesicles the size of a pea or smaller appear and burst, evacuating a cloudy, serous fluid. The affection runs its course in from twelve to twenty days without causing any serious disturbance of the general condition. Staphylococci have usually, though not always, been discovered when the fluid of the vesicles has been examined, and Koblanck has regarded the *Staphylococcus aureus* as the source of the infec-

tion. Epidemics of the disease sometimes occur in maternity hospitals where the conditions are favorable for the transmission of the contents of the vesicles from one child to another. This may easily occur through the common use of various articles employed in the care of the children, but may also be effected simply through the person of the nurse. Kownatzki describes such an instance in the *Münchener medizinische Wochenschrift*, September 24, 1907, in which, after an epidemic of pemphigus, the disease was practically exterminated through strict isolation of the patients, but broke out again when the precautions were relaxed, and did so under circumstances that made it clear that one nurse in particular had been the means of carrying the infection. The necessity for isolating such cases is apparent when they occur in institutions, and even though its etiology has not been definitely established the disease is evidently one to be readily controlled by precautions such as are used in cases of erysipelas for example.

Tuberculosis and the Induction of Abortion.

In a recent number of the *Beiträge zur Klinik der Tuberculose* (Bd. VIII., Hft. 2), van Armstel reports the results of extensive observations on the relation of tuberculosis and abortion. He has not found that the lung disease causes abortion except in its last stages. If the disease in the mother is considered curable the author would advise abortion as soon as possible, in order to conduce to her recovery, but if there is no hope of recovery the pregnancy should be allowed to go to term in the interest of the child. The most notable of van Armstel's views are formulated in the following propositions: Pregnancy, labor, and the puerperium exert a bad influence upon an already existing phthisis. When an hereditary weakness of resisting power exists pregnancy often causes the development of tuberculosis. Placental infection rarely occurs, but the children of a tuberculous mother have less resistant power and less prospect of life both before and after birth than normal, and are predisposed to pulmonary tuberculosis. The medical advisers should warn women who suffer from phthisis, and who propose to marry, of the dangers which marriage will bring. When marriage has occurred the physician should warn against the danger of permitting pregnancy to occur. Van Armstel even counsels abortion in such cases if conception should chance to occur, and he says the indication for abortion is the more pressing the less advanced is the tuberculosis, because of the increased chance of preserving a relatively sound state of health in the woman. If, however, there is no hope of recovery or arrest of the disease in the mother, the pregnancy may, in the interest of the child, be allowed to go on to term.

Abolishing a Dirty Practice.

In our news columns a few weeks ago it was stated that the progressive Health Commissioner of Pennsylvania, Dr. Samuel G. Dixon, had published an order forbidding Pullman car porters to brush the clothes of passengers in the aisles of the cars. The endurance of this noxious custom for so many years is an evidence of the long suffering patience of the American traveling public. Apart from its glaringly unhygienic features, this scattering of dust through a car and over the already sufficiently dirty and uncomfortable passengers has long been voted an unmitigated nuisance. The practice was instituted by the rapacious porters as a means of extorting dimes and quarters from their unwilling victims and has been endured simply because no one wishes to make himself conspicuous by audible protests. It is worse than useless as a means to cleanliness, for the clothes of those first brushed are as dirty as before by the time the whole carload has been curried, and what dirt has not settled back on the external parts of the travelers has filled their nostrils and lungs—not only the dust of the road, but the germ-laden accretions from the garments of men in all conditions of health and disease. Other State boards of health, that have the authority to issue and enforce orders for the protection of the health of the communities they serve, will do well to follow the example of Pennsylvania in putting a stop to this most insanitary and in every way objectionable practice.

News of the Week.

Quiet in the Coroner's Office.—For the first time in many years, according to those in charge at the Coroner's office, a period of almost three-quarters of a day elapsed without any sudden or suspicious deaths being reported. The interval of inactivity began at 2 o'clock on last Saturday afternoon and lasted until 9 o'clock Sunday morning, which makes the occurrence all the more unusual, as Saturday night is usually very prolific in tragic deaths. No suicides or murders were reported during the twenty-four hours ending at 2:45 P.M. Sunday, which was also almost unprecedented.

Imprisoned for Selling Cocaine.—A druggist on Mott street in this city was sentenced on Monday by the justices of Special Sessions to six months' imprisonment in the penitentiary on Blackwell's Island for selling cocaine. This is the heaviest sentence that has yet been imposed for this offense. In April last the same man was twice convicted, but only a nominal fine, with the option of a few days in prison, was his punishment at that time.

Titled Chinese Opium Users.—According to the press despatches, the efforts to restrict the habitual use of opium in China are being pushed with considerable vigor. The names of several princes and other high officials are given, who, it is alleged, have been suspended from their court positions for failure to give up the drug during the six months allowed by the imperial decree of last year. This provided that functionaries who were not able to abandon the habit during the prescribed period would be allowed to retain their rank, but would have to retire from office. Those who should falsely pretend to have abandoned the drug and continued to use it in secret would lose both rank and office.

The Long-suffering Prune.—The unpopularity of prunes as a staple of boarding-house dietaries will probably be still further increased through the newspaper announcement that an eminent French scientist has declared that there is a connection between the use of prunes and baldness. The "professor" is stated to have discovered a new kind of microbe which flourishes in prunes and figs and other dried fruits, also in the human hair and in the feathers of certain birds, notably parrots. This parasite, while not definitely causing the hair to fall, is alleged to predispose to baldness.

Plague.—Deaths from plague and new cases of the disease continue to be reported from Oran, Algeria.

Yellow Fever in Cuba.—Although there are still cases of the disease outside the city, Cienfuegos

itself has been freed from yellow fever under the régime of the United States health authorities.

Cholera.—The cholera situation in Russia is increasing in gravity, and every province that suffered from the famine of last year is in the grasp of the disease. The cholera epidemic in Tokio is gaining alarming proportions in spite of the efforts of the authorities. The disease is also spreading in Korea.

Hospital Closed by Smallpox.—The Hospital of the University of Pennsylvania has been closed by order of the Philadelphia Bureau of Health by reason of the admission to the wards of a sailor from an incoming vessel, who was subsequently found to be suffering from smallpox. Every person within the hospital was vaccinated, and none was permitted to make his exit and none permitted to enter until the period of incubation had elapsed and the hospital had been disinfected.

Anniversary of the Charity Organization Society.—The New York Charity Organization Society will hold a convention of settlement and social workers on November 19, 20, and 21 in this city to mark the twenty-fifth anniversary of its existence. An open meeting will be held at Carnegie Hall on the evening of November 19, at which Gov. Hughes will speak. Tickets for this meeting may be had by applying to the Charity Organization Society. There will be six other sessions of the convention.

A Large Fee.—The physician in attendance during the last illness of a wealthy Chicago woman, who died several years ago in California, has been awarded a verdict against the estate for $100,000 for professional services. The claim was made by virtue of a contract made with the patient that he should attend her until the time of her death, and should then receive $100,000 by her will. The physician had given all his time to the patient during several years, and the jury allowed the full amount sued for.

Fire at the Post-Graduate Hospital.—On Friday of last week the Post-Graduate Hospital was endangered by a fire in the storeroom in the basement of the seven-story building. The patients were brought down from the upper floors, but the members of the house staff had put out the fire with hand extinguishers before the arrival of the firemen. The fire was caused by defective insulation of the electric wires.

Gift from the German Emperor.—At the fair of the German Hospital and Dispensary Association in Jersey City last week a portrait of the German Emperor, with his autograph attached, was received through the German consulate.

Christian Scientists Convicted.—A jury in Mount Holly, N. J., last week rendered a verdict of guilty with a recommendation to mercy in the case of two Christian Scientists charged with manslaughter. They had refused to employ a physician in the illness of their seven-year-old son until within a few hours of the child's death.

New Health Department Building in Brooklyn.—Ground has been broken for the new office building of the Brooklyn Health Department at the junction of Fleet street, Willoughby street, and the Flatbush avenue extension. Dr T. R. Maxwell, head of the Brooklyn department, officiated. The building will be of white marble and six stories in height.

Chicago School Children Inspected.—According to the weekly bulletin of the Chicago Health Department, 17,820 children were examined during the first twenty schooldays by the medical inspectors of the health department, and of this number 1,476, or 8.3 per cent., were excluded from attendance at school on account of the existence of the following contagious diseases: Tonsillitis, 315; pediculosis, 378; impetigo contagiosa, 188; scarlet fever, 120; scabies, 99; diphtheria, 84; whooping-cough, 66; purulent sore eyes, 45; measles, 42; mumps, 40; chickenpox, 32, and tuberculosis, 3. Of the 456 exclusions during the week 105 were afflicted with tonsillitis. Microscopic examination of cultures from 66 of these cases showed 7 of them to be diphtheria.

Opening Exercises of the Chicago College of Physicians and Surgeons.—The Medical Department of the University of Illinois was opened October 1 for the session of 1907-8. The address was delivered by Dr. L. Harrison Mettler, who selecetd for his subject, "Art and Science as Applied in the Practice of Medicine."

Sanatorium at Naperville, Illinois.—A building, which will accommodate ten female patients, has just been completed at the Edwards Sanatorium, Naperville. This institution, designed for the treatment of early cases of pulmonary consumption, was created a year ago by Mrs. Edward L. Gaylord, as a memorial to her husband. Mrs. Gaylord recently deeded the entire plant, with forty acres of land, to the Chicago Tuberculosis Institute. There are ten free beds, the other sixteen patients paying $10 per week, on an average.

Dr. Robert Coleman Kemp has been appointed Visiting Physician in Gastrointestinal Diseases to the Red Cross Hospital.

New Jersey Board of Health Conference.—The second annual conference of the New Jersey State and local Boards of Health will be held in the State House at Trenton, October 25 and 26, 1907.

To Exterminate Mosquito Larvæ.—In order to check the multiplication of mosquitos in Pittsburg, the Bureau of Health of that city has placed 70,000 sunfish in the park lakes.

Ambulance Accidents.—A Mount Vernon trolley car on October 11 collided with a Mount Lebanon Hospital ambulance at Melrose avenue and 156th street. The surgeon was thrown heavily, suffering severe contusions and a sprained ankle, and the ambulance was wrecked. In a similar accident in Newark, at the corner of Bergen and Bank streets, the ambulance was badly damaged and the surgeon was severely injured about the body and legs. The driver also received several wounds.

Gift to Philadelphia Hospital.—The German Hospital of Philadelphia has received a donation of $5,000 from Mrs. Amelia H. Harjes of Paris to establish a free bed in memory of her mother, Bertha Everts Hessenbruch.

Demands Exoneration.—Dr. Francis D. Patterson, who resigned the position of surgeon to the Police and Fire Departments of the city of Philadelphia, has asked for an investigation on the part of the censors of the Philadelphia County Medical Society of charges made by the Director of Public Safety that he had been unduly active in the prosecution of claims for damages against the Rapid Transit Company. Dr. Patterson has made an unequivocal denial of the charges and insists on a retraction by the Director.

The Late Dr. Seneca D. Powell.—At a regular meeting of the Medical Board of St. Mark's Hospital, held October 1, 1907, the following resolutions were adopted: "*Resolved*, That in the death of our late friend and associate, Dr. Seneca D. Powell, the hospital has sustained a loss which we deeply mourn.

His great ability as a teacher and voluminous writer commanded the respect and admiration of the entire profession. His devoted work and experiments in behalf of medical education connected his name most prominently with the teaching of medicine and surgery. But, above all, his fearless honesty of purpose and his exquisite gentleness of character and manner so endeared him to his associates that we, his colleagues and friends, feel in his death a personal bereavement. *Resolved*, That we tender to his family our sincerest sympathy in their bereavement, and that a copy of these resolutions be spread upon the minutes of this Board and published in the medical press." (Signed) Reynold Webb Wilcox, President; Ignatz Morvaj Rottenberg, Secretary; Carl Heck, President, Board of Trustees.

Obituary Notes.—Dr. JOSEPH GRAHAM of Charlotte, N. C., died on August 13, at the age of seventy years. He had suffered for forty years with stricture of the esophagus, and this was complicated by a chronic pleurisy. Death resulted from inanition. Notwithstanding his age and his serious ailments, he was in active practice until seven weeks before his death. He was a graduate of the Jefferson Medical College in 1859, and practised in Charlotte continuously from that time until shortly before his death. He was one of the best known and most honored practitioners in the Old North State, having served as a member of the State Board of Medical Examiners, and was at one time president of the North Carolina State Medical Society.

Dr. LILLIAN ALICE WILLIS of Jersey City died on October 7, at the age of forty-three years. Dr. Willis was born at Trumansburg, N. Y., and had practised in Jersey City for over twenty years.

Dr. P. H. ELLSWORTH of Hot Springs, Ark., died on September 30 of a gastric disorder. Dr. Ellsworth was born in Hatley, Canada, in 1838, and was graduated from Rush Medical College in 1861. He served through the Civil War as surgeon of the 106th Regiment, Illinois Infantry, with the rank of major. He had practised in Hot Springs for about forty years.

Dr. EDWARD R. JEBB of Battle Creek, Mich., died on October 3, at the age of fifty-six years, after an illness of three weeks. He was born in Bristol, England, but when twenty years of age came to Toronto and was graduated in medicine from Queen's University. For a time he practised in Climax, Mich., and Benton Harbor. For the last ten years he had been a resident of Battle Creek.

Dr. WILLIAM H. BERTH of Providence, R. I., died suddenly on October 3, at the age of thirty-one years. He was a native of Providence, and was graduated from Georgetown University in the class of 1903.

Dr. JOHN M. PRILAY of Bangor, Me., died on October 3, at the age of forty-six years. He was a native of Newport, Me., and was graduated from the Hahnemann Medical College of Philadelphia in 1885. Since that time he had practised in Bangor until about two years ago, when ill health compelled him to give up active work.

Dr. CLARENCE E. BARBER of Warren, Wis., died on October 2 in Salt Lake City of tuberculosis. Dr. Barber was thirty-nine years of age, and had practised in Warren for about sixteen years. Some months ago his illness compelled him to give up practice, and since that time he had been traveling in the West.

Dr. C. BRET POOLE of Lowell, Mass., died on October 8, at the age of thirty-eight years. He was born in Otter, N. Y., and was a graduate of the Baltimore College of Physicians and Surgeons.

Correspondence.

ANTERIOR POLIOMYELITIS AND COWS' MILK.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Epidemics of acute anterior poliomyelitis have been so often recorded that its infectious origin seems a probability, while many of the causes ordinarily given may well be predisposing. The percentage of cases occurring during the different periods of infancy is, at least, somewhat suggestive of cows' milk as a possible medium of infection. For instance, cases are rare during the early months of the first year—a time when many infants are on the breast. The greatest number of cases is seen during the second year—a time when cows' milk becomes the staple food of infants. The frequency diminishes during the third and the fourth and fifth years, after which only a small percentage of cases occurs.

In short, the rise and decline in the percentage of cases seems to be more or less parallel with the increase, height, and subsequent decrease in the amount of cows' milk used during the different periods of infancy. Epidemics, moreover, occur principally during the warm months or those most favorable to the growth of different microorganisms in the milk. The attacks, also, frequently follow or are accompanied by disturbances of the digestive tract.

If the inference that the disease is conveyed by cows' milk be correct, sterilization would prevent or check the spread of epidemics, and prophylaxis is most important, as the disease so frequently results in permanent disability despite all efforts to the contrary. This letter is written merely as a suggestion, in the hope that by cooperation some light may be thrown upon this condition, which is so prevalent and distressing at the present time. Such a result might be obtained if physicians would report to some responsible authority (as the Board of Health) every case coming under their observation, with a statement of the condtion in which the milk was given; that is, whether raw, pasteurized or sterilized, or whether the infant was breast-fed exclusively. Printed postals would facilitate reporting.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SANITARY MATTERS—CONFERENCES—A NEWCASTLE PROGRAM—INTERNATIONAL HYGIENE AND DEMOGRAPHY—OUR EXHIBITION OF QUACK MEDICINES AND LECTURES ON THEM—THE "BELOVED PHYSICIAN"—OPENING OF THE SCHOOLS—INQUEST.

LONDON, September 27 1907.

Omnia Sanitas expresses in brief the topics of the day—or at any rate of the conferences, congresses, and associations that have so busily occupied themselves this autumn with everything relating to public health. And these meetings are not yet over. At home and abroad they are going on and others are projected. Here in London it is proposed to hold in November a preliminary conference of sanitary authorities with a view of uniting them in a sort of central union. This proposal comes from Newcastle-on-Tyne and may prove another important "Newcastle program." Dr. H. E. Armstrong, the able and strenuous Medical Officer of Health in that northern town, is the originator of the scheme and an executive committee has been formed to promote it. A circular letter has been addressed to the chairmen of the sanitary committees of county councils, boroughs, and port sanitary authorities. This circular remarks on the want of conformity of action of the several authorities—a fact which has long been notorious and has sometimes seemed the despair of sanitary reformers. Time and energy have been expended in the vain endeavor to carry out broad measures, formulating model codes and overcoming the opposition of vested interests. This last point is perhaps the core of public health reformation. We so often see committees failing to support their Medical Officer of Health because his recommendations affect the pockets of some of the members. It would seem, therefore, that the first thing to do would be to educate the ratepayers so as to secure independent committees. Dr. Armstrong's scheme is to set up a central body, which should represent every sanitary authority in the kingdom. This body, which some of its supporters dub a sanitary parliament, perhaps because they mean it to be another talking machine, certainly will not be legislative, and if it reaches maturity it may be hoped that it will prove more businesslike than most of its constituent parts. Its first duty would appear to be advisory and as its recommendations would represent

the numerous local administrations they would come before the government with more authorities than any of these bodies. They might, too, have an important influence over local boards. The public health acts might be submitted to close expert criticism and the defects with which medical officers have to contend would be brought more forcibly before the public and the legislature. Perhaps in the not too distant future the acts might be consolidated and added to so as to form a national sanitary code. The questions that might be profitably discussed by such a body as proposed are so numerous that before the conference in November it seems desirable that the Newcastle program should be more definitely defined.

The dispute at Southend-on-Sea as to the salary of the Medical Officer of Health is a sample of several others. Some of the vacancies will shortly be advertised, but the medical journals will refuse to insert the notices. It remains to be seen whether any qualified men will step into the shoes of those who have been treated unjustly and even cruelly.

Some echoes of the International Congress of Hygiene and Demography are reaching us. It was opened in Berlin on the 23d and your Berlin correspondent will no doubt furnish you with an account of its proceedings. I will, therefore, only allude to what is commented on here. Major Ronald Ross submitted a paper on "Malaria," and other English congressists are contributing on tropical subjects. Mr. Aldridge of Leicester, secretary of our National Council for Dwellings Reform, explained what has been done in some of our districts and how far he thought the measures might be applicable elsewhere, and both French and German members discussed his statements.

In connection with the congress a correspondent informs me that an exhibition is open of a very interesting kind. A notable section sent by the Health Office of Rio de Janeiro shows the methods of dealing with yellow fever and malaria, while another consists of a display and exposure of quack medicines, old and new, I suppose of German manufacture only. Lectures are also delivered on the pretences of magnetopathists, occultists, and other irregular practitioners. The example is one which might very well be followed by one of our sanitary institutions or even by the British Medical Association. Such an exhibition would make a popular section in the annual museum. But I am induced to refer to this chiefly by the action of one of our newspapers, which makes it a text for censuring the profession for not "more emphatically proclaiming aloud the truth about quackeries." Is not this an apt illustration of the proverb that none are so blind as those who will not see? All the time this very newspaper is selling its columns and its influence to fraudulent advertisers of quack concoctions. Is it the price of the advertisements that hides the fraud or hypocrisy doing homage to virtue? Telling doctors to speak out about quackery, forsooth!

Was the author of the third gospel a physician? The Luke tradition has for some time been contemptuously rejected by the German "higher critics," but Professor Harnack has, after several years devoted to reinvestigating the question, come to the conclusion that the tradition is based on historic fact. In his work which is now translated he declares we can assert now that in A. D. 30 to 70, on the soil of Palestine—particularly in Jerusalem—the Christian tradition took the essential form it presents in its later development. From a strict scrutiny of the text of the gospel he concludes that Luke was a Hellene by birth, a physician, a companion and fellow worker with Paul. The date of composition of the Acts he puts as about A. D. 80—certainly sometime between the fall of Jerusalem and the Domitian persecution. Probably Luke was then fifty or sixty years old. His use of medical terms and the prominence he gives to miracles of healing in both the gospel and the Acts show that he was well versed in the medical science and practice of his time.

Next Tuesday is the opening of the London schools and the details of the ceremonies on the occasion are almost all complete. At Guy's work will begin without special ceremony, but on the Friday following the Physical Society will open and it is pleasant to hear that Sir Samuel Wilks will preside on the occasion. This venerable teacher of Guy's lately issued a pamphlet consisting of a revision of an address he had given in connection with the subject of vivisection.

At St George's Hospital a tablet to the memory of the late Dr R Barnes will be unveiled in the Robert Barnes Laboratory. A lecture by Dr. Swart will follow and a dinner in the evening, at which Sir H. M. Ellis, Director-General of the Royal Naval Medical Department, will preside. At St Mary's Hospital Professor Osler will give the address and distribute the prizes. At the Middlesex Mr Henry Morris, President of the Royal College of Surgery, will distribute the prizes and Mr. Foulerton deliver the address. At King's College, besides an address at the distribution of prizes, there is announced for the next day a special introductory lecture by Prof. Thompson on the study of embryology during the nineteenth century. This may seem hardly a theme for an introductory, but you must remember that freshmen are a very small minority on these occasions, which are rather opportunities for meeting old students and renewing old associations. Moreover of late years the discourses have had a tendency to appeal to the public so that sanitary matters threaten to displace the more strictly medical ones, or at least the relations between the profession and the public. In this year's announcements there is one lecture entitled "Res Medica, res Publica."

A more distinct appeal to the public, or rather that part of it specially interested in hospitals, is the substitution by Bart's, the London, and some other hospitals of a dinner, reception, or some kind of gathering to which supporters of the particular institution and friends of students can be invited.

The opening of the session at University College corresponds with the opening of a new era in the history of the medical school which will begin its work in the new buildings provided by the generosity of Sir Donald Currie. Sir Richard Douglas Powell will deliver an address, at the conclusion of which medallion portraits of the late Mr. Christopher Heath and Dr. G. V. Poore will be unveiled in the entrance hall. The students' dinner will be held in the library, Sir W. R. Gowers in the chair.

A singular prosecution for selling poison in drugs has followed the death of a child who got hold of a bottle of tabloids containing strychnine and swallowed fifteen or sixteen. The tabloids were bought at a chemist's store, the bottle was not labeled poison, and the Pharmaceutical Society prosecuted the firm and obtained a conviction. The defense was that these tabloids were always thus sold; but the magistrate could not recognize such a custom, as it was in direct opposition to the Act. The firm of store chemists thereupon bought drugs at various shops and, having secured some at an establishment belonging to an ex-president of the Pharmaceutical Society, summoned him in turn and obtained a conviction. There was no pretense of an attempt to evade the Act, but the magistrate was obliged to convict, as the letter of the law had not been complied with. It was pleaded that the child ought not to have had access to the tabloids and that as many antibilious pills would have been just as fatal.

OUR PARIS LETTER.

(From Our Special Correspondent.)

URETERAL ANASTOMOSIS—OPERATIVE TREATMENT OF BILIARY CALCULUS—ENDOSCOPY OF THE UTERUS—TREATMENT OF CANCER BY THE HIGH FREQUENCY CURRENT—BACTERIOLOGY OF ACUTE ARTICULAR RHEUMATISM—DEATH OF PROFESSOR GRANCHER.

PARIS, August 31, 1907.

At a recent meeting of the Société de Chirurgie, M. Pierre Delbet opened an interesting discussion on ureteral anastomosis. After referring to Auvray's case of implantation of the ureter in the rectum, he related two personal cases of a similar nature. In both of these the results had been successful. The great danger of this operation is an ascending infection of the kidney, but this occurs very often even when no operation is attempted. M. Legueu reported the case of a woman with cancer of the bladder who was suffering from stenosis of the ureter and renal trouble, consequent upon retention. He grafted one of the ureters into the rectum and the woman survived the operation four years, being entirely relieved of the trouble which had called for intervention. At the autopsy the implanted ureter was found much narrowed and the corresponding kidney completely atrophied. The speaker said that the success of these operations depended wholly upon the technique employed. The operation was a very difficult one, for immediate and perfect union was indispensable, and such union was far from being the rule. When it was not obtained, the result was a certain degree of inflammation, with subsequent narrowing of the ureter. Permanent catheterization of the ureter was an indefensible procedure. M. Ricard described a simple method of ureterovesical anastomosis. After having freed and divided the ureter, he then made a lateral section, about a centimeter in length, of the tube which permitted of folding back of the ureteral wall, which was fixed by fine catgut sutures; then the invaginated tube was attached to a buttonhole incision in

the bladder wall, and the bladder itself was united to the renal pelvis to prevent a tearing loose of the attachments. Dr. Delbet said that he had twice made a new implantation of the ureter into the bladder. In studying the results of these operations he had employed with much satisfaction Luys' method of separation of the urine. In one case he had found the operative results excellent, the newly implanted ureter giving about as much urine as the other side. In the other case the anastomosed ureter did not give a single drop of urine, showing that the ureter was obliterated and the corresponding kidney atrophied.

M. Terrier reported five interesting cases of Kehr's operation for biliary calculus and for non-calculous cholecystitis and angiocholitis. This operation consists in extirpation of the gall-bladder and cystic duct, followed by drainage of the hepatic duct. The results were good in these five cases, owing, the speaker said, to the fact that the biliary passages were dilated, this condition being favorable to the success of Kehr's operation. M. Picqué said he had performed this operation successfully in the case of a woman, 45 years old, who had two stones in the ductus choledochus. These were shelled out of the wound, resulting from resection of the cystic duct, and removed at the same time as the shriveled and suppurating gall-bladder. The operation was followed by drainage of the hepatic duct, and the patient made an excellent recovery.

The subject of endoscopy of the uterus was discussed at a meeting of the Hospital Internes Society. With an instrument constructed on the model of Luys' urethroscope, M. David had been able in several cases to diagnose in the puerperal uterus retention of placental remains, fibroids, and traumatic tears. The author believed this method was destined to render great service where other modes of clinical investigation were insufficient.

M. de Keating-Hart read a paper at a recent meeting of the Academy of Medicine on the action of high-frequency sparks in the treatment of cancer. The author employs prolonged and forcible projection of powerful sparks given off by an Oudin resonator. The results obtained were relief, partial or complete, of the pain and often a suppression of the hemorrhages. The late results varied according to the seat, more or less superficial, of the tumor and the state, more or less advanced, of the disease. But there was always a retardation in the growth of the tumor, together with a notable improvement in the general condition.

The bacteriology of acute articular rheumatism was the subject of an interesting communication presented to the Hospitals Medical Society by M. Triloubet. In a man suffering from rheumatic polyarthritis, there developed successively a double bronchopneumonia, a double pleurisy, aortitis, and endopericarditis. The author found in the sputum, the pleural effusion, and the blood the diplostreptococcus, growing in both aërobic and anaërobic cultures, described by himself and M. Coyon in 1897. The same microorganism was found in sections made from the pericardium, appendix, and ampulla of Vater. The speaker said that a rheumatic subject was always liable to attacks of the disease by reason of the presence in the digestive tube of this causal organism. The greater number of cases of acute articular rheumatism were, he said, referable to a catarrhal condition of the digestive tract, and were due therefore to an intoxication of intestinal origin. All degrees of this intestinal toxemia might be encountered, from a slight ephemoral articular effusion to the most terrible and painful involvement of the joints, and even dissemination to the neuraxis (chorea and cerebral rheumatism).

Professor Grancher has died, at the age of 64 years, stricken down in a few days by a grippal pneumonia. With him disappeared one of the most striking and illustrious personalities of the medical world. The important works of this master on tuberculosis are too well known for it to be necessary to recall them. It is known how deeply he studied auscultation of the lungs and the subject of pleurisy, and with what eloquence he argued in support of the curative isolation of hospital cases of tuberculosis. Since 1883 Grancher was Professor of the Diseases of Children at the Faculté. The precision of a style always simple and absolutely correct, an impeccable method of exposition joined to concision constituted the great qualities of Grancher and explained the real power of persuasion of this master and the authority early acquired and readily conceded to him by all. The work of the preservation of children from tuberculosis was founded by him; its end was to cure from this scourge children as yet uninfected but the issue of tuberculous parents. This work proved the noble qualities of heart and the generous philanthropy of him who has just gone from us.

OUR LETTER FROM VIENNA.

(From Our Special Correspondent.)

OCULAR PALSIES AND DIABETES INSIPIDUS—GARRULITAS VULVÆ—X-RAY FEVER—RADIOTHERAPY OF LEUKEMIA—FORMALDEHYDE DISINFECTION—AN EPIDEMIC OF SMALLPOX.

VIENNA, September 15, 1907.

An interesting case was recently reported by Prof. Schlesinger. The patient was a man of twenty-two years, who had paralysis of the eye muscles and diabetes insipidus supervening in the course of an attack of scurvy. The paralysis affected both abducentes nerves and in a degree also the left oculomotor (superior and inferior recti muscles). The other cranial nerves were unaffected and there was no paralysis of the extremities. Symptoms of cerebral compression and general symptoms, with the exception of vomiting, were absent. The ophthalmoscope showed numerous points of retinal and choroidal hemorrhage surrounding the papilla on each side. Of especial interest was another cerebral symptom appearing at the very beginning of the brain affection, viz. polyuria. The amount of urine increased progressively, in the course of about a week, from one liter to more than twenty liters a day. At no time was there any sugar or albumin; the sp. gr. of the urine was about 1.001. This case confirmed the fact that lesions of the structure of the posterior convolution may be followed by diabetes insipidus. The patient was put upon strychnine, but a reduction in the polyuria was obtained only after restricting the intake of fluids.

Heinrich Rotter has reported a case of garrulitas vulvæ in a woman twenty-five years old, who had had two children and two miscarriages. With the first childbirth there was a tear into the bowel which was not repaired at the time. Since then the patient had noticed the frequent noisy escape of gas from the vagina. The lesion was one typical of such cases. When the woman was in the knee-elbow position the vagina became distended with gas, and when she sat down it escaped with noise. The bacteriological examination showed the presence of a gas-forming bacillus. The operation, which gave relief, consisted in an anterior colporrhaphy and a colpoperineorrhaphy. Rotter believes that mechanical factors are most active in the production of garrulitas vulvæ, though he would not exclude entirely Veit's theory of the action of gas bacilli.

Alfred Huber reports a case of elevation of temperature occurring in a patient under *x*-ray treatment. The case (in Rona's clinic) was one of lupus erythematosus in which fever of an intermittent type occurred.

Alfred Decastello and Robert Kienböck have made a number of interesting observations on radiotherapy in the treatment of leukemia. The cases studied were 18 in number, 10 of myelogenic and 8 of lymphatic leukemia, several of which had been under treatment for a long time, even as much as two and one-half years. In myelogenic cases (in 90 per cent. of which substantial improvement may be looked for), the treatment should be persevered in for a long time, but in spite of the apparent improvement relapses are apt to occur; sometimes the efficacy of the treatment appears to wear itself out, and an acute exacerbation of the disease may result fatally. The prognosis appears to depend less upon the duration of the disease than upon the acuteness of its course. In lymphatic leukemia a general improvement is often noticed, but it is seldom that any betterment in the anemia occurs. The prognosis of this form of leukemia depends largely upon the degree of anemia present. In general the disease, under radiotherapy, runs a very chronic course with slight tendency to relapse, so that the prognosis as regards length of life is better in this form than in myelogenic leukemia. The authors conclude that under the influence of radiation substances are produced which are not directly leucolytic, but which hinder the new formation of granular cells, though probably not of lymphocytes.

Two military surgeons, Doerr and Raubitschek, recently described, in a paper before the Gesellschaft der Aerzte, a simple and inexpensive method of house disinfection. This consists in the use of equal parts of water, formalin, and potassium permanganate. For every 100 cubic meters of space, two kilograms of each of these three substances are required. Several vessels should be used, and into them the permanganate is first placed, and when all is ready the mixture of water and formalin is added, the room being immediately vacated and closed. Metal vessels should be used, and they should be of good size, for the mixture foams considerably, a vessel of twenty-five liter capacity

being none too large for a kilo of each of the substances. Six hours is sufficient for complete disinfection. Then the doors and windows are to be opened and the formalin vapor expelled or neutralized with ammonia. The cost is about 4 crowns (80 cents) for every 100 cubic meters. The method is to be recommended by reason of its simplicity, cheapness, and freedom from danger of fire. The reaction upon which it is based was discovered by Evans and Russell in Washington.

We are now in the midst of a smallpox epidemic. Every year there are isolated cases of the disease in Vienna, but because of the very general resort to vaccination the cases have hitherto been few in number. Of late years, however, the antivaccinationists, inspired by the "nature healers," have been active with the result that the general population has become in a measure unprotected. About ten days ago some cases of smallpox occurred, imported probably from the country, and the disease spread with great rapidity. The sanitary authorities have done everything in their power to master the epidemic, but they have to contend with the indifference or active opposition of the families of the sick. The newspapers have tried to suppress the accounts of the epidemic, for this is the season when many strangers are in Vienna and the shopkeepers and hotels would suffer if it became known that smallpox was so prevalent. The city authorities have appointed a special corps of medical inspectors and have opened a number of vaccination stations. The latter are visited by throngs, and the number of vaccinations and revaccinations is increasing daily. The public has suddenly become convinced of the protective power of vaccination, and there is a growing sentiment in favor of a compulsory vaccination law.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 3, 1907.

The Treatment of Typhoid Fever with Specific Sera, Filtrates and Residues (Vaughan).—M. W. Richardson reports the results of his studies of specific therapy in 130 cases of typhoid fever extending over a period of eight years. His work has brought out the following facts: (1) Specific therapy, confined to the original disease, increases, apparently, the tendency of the disease to relapse. (2) By therapeutic inoculation, however (Vaughan's nontoxic residue), continued into convalescence, the relapse in typhoid fever can be largely eliminated. This claim is made with much assurance, but is, of course, subject to confirmation by observation upon a much larger series of cases. If relapses can be prevented then it follows almost certainly that mild typhoid infections can be aborted. This study would show, furthermore, (3) that to get the best results cases must be seen as early as possible in the infection, but (4) that an early diagnosis in typhoid is oftentimes impossible, and that, for this reason, specific therapy suffers under a severe handicap. (5) Antityphoid serum was no more effective than filtrates and residues and was infinitely more expensive. (6) Typhoid filtrates may exert a powerful effect upon the clinical course of the typhoid process, their use being followed in many instances by chills, or rise in temperature and pulse, these being followed in their turn, oftentimes, by marked fall in temperature, pulse, and respiration, and a general improvement in the clinical picture. The nature of these reactions is still unknown. It is hoped that further study, especially that of the opsonic index, in connection with these reactions, may give valuable information concerning their nature. (7) The nontoxic residue of the typhoid bacillus as prepared by Professor Vaughan seems to make the typhoid process longer, but milder. As stated above, it is apparently very effective in the prevention of relapses.

New York Medical Journal, October 5, 1907.

Adhesive Plaster for the Cure of Certain External Diseases and Lesions.—The use of ordinary adhesive plaster is commended by M. B. Hutchins, subsequent to the caustic or electrolytic destruction of tissue. The plaster is fitted closely to the eschar or crust and prevents too free oozing. It is renewed as often as soiled, hastens the softening and separation of the eschar, and greatly shortens the time required for healing. Some cases have been dressed with the plaster directly on the wound and periphery up to final healing. The plaster is often a valuable substitute for the familiar salicylic acid plaster. The most striking results have followed its use in boils and subcutaneous abscesses. It apparently closes in the infection so that the usual "crop" of boils does not follow. Also in subcutaneous abscesses equally good results have been obtained. The abscess is punctured and all the pus is pressed out, the pressure being continued till blood and serum begin to flow from the distended capillaries. A small piece of cotton is then applied and covered with the adhesive plaster over a sufficient area to insure some moisture beneath. Serous flow is constant, the incision cannot heal or crust, infection rapidly yields and granulation begins to repair the damage. The incision must be probed and kept open each day until fluid no longer appears. The dressings seem to owe some of their value to their exclusion of the air. Histories of eleven cases illustrate the points made by the author.

Incarceration of the Retrodisplaced Uterus.—C. W. Barrett's conclusions on this topic are as follows: (1) Although pregnancy may be a means of correcting some cases of retrodisplacement, each case of pregnancy and each case of retrodisplacement has added clinical significance when the two conditions are combined. (2) With the onset of pregnancy a retrodisplaced uterus should be returned to normal position as soon as possible and supervised during the early months of pregnancy. (3) An irreducible retrodisplaced gravid uterus may be given time to rise out of the peivis with growth if symptoms of early or late incarceration do not present. (4) An irreducible retrodisplaced gravid uterus that shows early symptoms of incarceration which might lead to abortion, or late incarceration, with its attendant evils, should be replaced by means of a celiotomy; the complications should be dealt with, and a radical operation should be performed to permanently cure the retrodisplacement. (5) Cases of late incarceration may be met in which gangrene, septicemia, peritonitis, uremia, etc., may contraindicate celiotomy for replacement and in which drainage of the bladder, drainage of the peritoneum, emptying of the uterus, or hysterectomy may be indicated. (6) The latter cases, now uncommon, will be rare indeed if the former teaching is generally accepted. (7) Careful celiotomy will seldom be the cause of abortion, but abortion will sometimes follow the operation as a result of incarceration. (8) This, instead of contraindicating an operation, points to the necessity of earlier operative measures. (9) This earlier resort to operative treatment appeals to the judgment of the patient and the physician when it can be shown that a radical cure of the displacement and its complications is feasible.

Intratympanic Operations Under Local Anesthesia.—M. J. Ballin gives the formulæ of the Bonnani, Gray and Haug mixtures, preferring the one first named (equal parts of phenol in crystals, menthol, and cocaine muriate), but late experience has convinced him that the use of cocaine alone is preferable. In the majority of intratympanic operations he uses a small syringe, injecting from 10 to 15 minims of a 1 per cent. solution, to which a little adrenalin has been added, into the superior wall of the external meatus. The main object, however, of the author's paper is to call attention to the method in acute cases, as in paracentesis. His techniques are as follows: The external auditory canal is first thoroughly cleansed with any antiseptic solution. A small piece of cotton is then placed into the canal so as to protect the drum against the ethyl chloride spray, which would otherwise cause too much pain. Having done this, a cleft speculum is introduced in such a manner that only the superior wall of the canal is exposed to view. With the aid of an assistant a spray of ethyl chloride is now allowed to play on this exposed surface, and as soon as the parts are well anesthetized the needle of the syringe is quickly introduced at the junction of the bony and cartilaginous canal, and the fluid slowly injected as already stated. Injection must be carried out very slowly so that infiltration takes place gradually, thus avoiding unnecessary pain. Having done this the little piece of cotton is then removed from the canal. After four to five minutes it will be noticed that the drum has assumed a more or less bleached appearance, and has also become so insensible to pain, that paracentesis can be performed without any annoyance to the patient.

Journal of the American Medical Association, October 12, 1907.

The Diagnosis of Exophthalmic Goiter.—L. F. Barker points out the diagnostic symptoms of exophthalmic goiter and their significance. Of the three generally recognized cardinal symptoms, the struma is present in the majority of cases, and, since we have learned to recognize slight degrees of goiter, it has been claimed by some to be constant. It may, however, be absent. The tachycardia is the most constant and important sign,

and the exophthalmos, while the most striking symptom when it occurs, is absent in about one-third of the cases. The muscular tremor of the disease is so frequently present that it might well be classed, with the above three, as a fourth cardinal symptom. It is rapid and vibratory, with from eight to ten oscillations a second, and is best seen by asking the patient to hold his hand with widespread fingers between the observer and the light. Other symptoms of diagnostic importance are throbbing of the carotid arteries and abdominal aorta, the accentuated cardiac sounds and murmurs, the characteristic anxiety and restlessness, the tiring on slight exertion in young persons, the Graefe sign and other ocular symptoms, the skin pigmentation and vasomotor unstability and the metabolic changes, loss of weight, etc. The diagnosis in typical cases is easy, but in the incipient and atypical cases there may be difficulty. Once the clinician has learned to observe the physical symptoms, the goiter heart, the psychic symptoms, etc., there is rarely room for doubt. An important part of the diagnosis is in the indications for surgical intervention. Barker has little faith in medical treatment, except it may be in modern serum methods, and he advises surgical operation, and the quicker the better, whenever a persistent thyreointoxication is clearly evident. The only contraindications in uncomplicated cases are a feeble heart with very high pulse frequency and pronounced psychic excitation. In these cases some preliminary medical treatment may be needed. In exophthalmic goiter the symptoms retrogress in conformity with the amount of gland removed.

Enterostomy in Postoperative Ileus.—F. D. Donoghue reports four cases of serious postoperative ileus treated by reopening the operative wound and by incision and puncture of the distended intestine, closing the multiple punctures with sutures, and providing not merely for permanent drainage in the cecum or ascending colon, but also for further treatment. He recommends this procedure even in cases in which the existence of profound shock would contraindicate operation in other than postoperative cases. While its indications cannot be clearly defined for all cases, it will be found, he says, a life-saving procedure in many cases ordinarily regarded as hopeless. Following recovery from enterostomy, the resulting fistula can be closed by suture or left to nature. As it causes little inconvenience and can be easily controlled by a pad on an abdominal belt, it may well be left alone.

Opsonins and Vaccine Therapy.—G. W. Ross defines opsonins as substances not yet isolated but existing in the blood, by means of which the phagocytes are enabled or induced to destroy bacteria. Their existence was one of Wright's discoveries, another was the technique by which we are able to measure the quantity of opsonins in a given blood, or the opsonic index. The application of these discoveries to the treatment and diagnosis of disease by means of the therapeutic inoculation of devitalized bacteria, or bacterial vaccines, he also credits to Wright. He offers the following classification of bacterial diseases in their relations to vaccine therapy: Class 1. This class comprises mostly chronic infections with persistent low opsonic index, due, it is supposed, to the absence of autoinoculation. The bacteria do not escape into the blood and increase the opsonins, hence the infection persists. In this class are included many tuberculous infections of glands, bones, joints, and early pulmonary tuberculosis. Here also we find acne, boils, felons, etc., and many persistent suppurative conditions. Class 2. In this class autoinoculation is the characteristic feature, and severe pulmonary tuberculosis is the type. The opsonic index fluctuates from high to low, and *vice versa*. Class 3. This class comprises the pure septicemias with probable generally lowered opsonic index, such as ulcerative endocarditis and puerperal septicemia. It is in the first class of localized infections that vaccine treatment has been most successful, and Ross reports an illustrative case showing the method of treatment. He also gives his experience with the treatment of boils, carbuncles and other staphylococcic infections by this method and also in the treatment of localized tuberculous conditions with new tuberculin. Lupus he finds rather more refractory than most other forms of localized tuberculosis, since we fail with it as often as we succeed. In early pulmonary tuberculosis he considers tuberculin a powerful agent for good, but in advanced cases it will be of little benefit. Streptococcic, pneumococcic, gonococcic, and other bacterial affections have been treated with success, and cases of cystitis, sinuses, etc., due to infection with *Bacillus coli communis*, have yielded to colon vaccine. He also reports a representative case of the third class of diseases, the septicemias and a case of ulcerative endocarditis, successfully controlled by streptococcus vaccine after antistreptococcus serum had failed. In conclusion, Ross states his opinion that inoculation with proper vaccines is a powerful aid in the treatment of many bacterial diseases. There is considerable difference of opinion concerning the relation of the opsonic theory to inoculation, but it is his opinion that while estimation of the opsonic index is often unnecessary such investigation has been and still is of great service in enabling us to determine the proper dosage and time for inoculation and reinoculation when we are in doubt.

The Venous Pulse.—A. R. Cushny and L. C. Grosh report investigations, both experimental and clinical, on the venous pulse. In their experiments on dogs, they registered the jugular pulse, as in their clinical observations, by means of a funnel receiver connected by an air tube to a very sensitive tambour, the writing end of the lever being in contact with the smoked paper of the kymograph. The carotid pulse was registered by means of a cannula in the carotid connected with a Hurthle's sphygmomanometer, and movements of the auricle and ventricle were registered by threads attached to them and to the membrane of the tambour which connected with another writing on the kymograph. In the jugular tracings, as a rule, a series of elevations separated by deep depressions is seen. The elevations are composed of three minor waves, which are marked *a*, *c*, *v* in their figures, after Mackenzie's method. The wave (*a*) has been ascribed by Mackenzie to the auricular contraction, and Cushny and Grosh find in their tracing that on projecting the auricular tracing on the jugular the middle wave corresponds exactly with the auricular contraction in its commencement and fall. The succeeding wave (*c*) was considered by Mackenzie to be a communicated impulse from the carotid, and others have supposed it communicated from the systolic stiffening of the aorta and the large arteries of the thorax. Morrow has lately revived Potain's view that this wave is produced in the heart during the ventricular systole and transmitted along the course of the vein. The authors' results indicate that this wave is not of local origin in the neck, but they are unable to say whether it arises in the heart or in its immediate neighborhood. They consider the question, however, as hardly of great importance as regards the clinical use of the method of recording the jugular pulse. The (*v*) wave appears to be dependent on the ventricular systole, and cannot be due to stasis as some have held, but their experiments do not suggest a perfectly satisfactory explanation of its mechanism. It may possibly be, as François-Franc has suggested, an indication of increased intraauricular pressure associated with ventricular relaxation. A number of other points of interest are noticed, and the clinical observations in four patients suffering with cardiac disorders are detailed, with special reference to the alterations of the venous pulse. The authors think that more attention might be given "to the form of the auricular wave in the jugular pulse, and that as much information as to the state of the heart may perhaps be derived from this source as has occurred from the study of its time relations."

Postoperative Intestinal Obstruction.—D. H. Craig reiterates his views, expressed in previous articles, as to the value of eserin salicylate for the prevention and treatment of early postoperative intestinal obstruction. He claims that the drug counteracts the spinal inhibitory impulses carried by the irritated splanchnics to the intestines and also sustains and stimulates the intrinsic intestinal musculature or its nerve supply, thus in both ways combating intestinal paresis. Its routine employment by himself and others has, he believes, demonstrated its safety in all cases where not contraindicated, even in children. The postoperative obstruction must be an early, not a late one, and his earlier suggestion was that in cases not demanding, from the nature of the work done, complete intestinal rest, a hypodermic injection of atropin sulphate should precede the administration of the anesthetic, and that on the operating table, as soon as it could be determined that it was not contraindicated, as above, often only from two to five minutes after opening the peritoneal cavity, a hypodermic injection of eserin salicylate in fresh solution be administered. Constant employment of this method for six years leaves him more enthusiastically in favor of its use than at the beginning. He gives his views regarding postoperative obstruction, its mechanism, diagnosis, etc., at some length, and reviews the objections that have been offered to his

method. Caution is given against using too large a dose. Craig uses 1/40 of a grain on the operating table and very rarely has occasion to repeat the dose. The keynote of success in the after-treatment of cases in which a prophylactic dose of eserin has been administered consists, he says, in letting the patient alone—it is purely expectant or symptomatic.

The Lancet, September 28, 1907.

Excision of the Parotid Gland with Preservation of the Facial Nerve; Its Possibility.—T. Cavdaurine reports the case of a girl of eighteen years with a mixed tumor of the parotid which was shelled out so as not materially to damage the nerve. Two months later it began to return and was soon a mass the size of a walnut. By patient dissection with small scalpels the nerve was successfully freed and held up by a loop of catgut, then the vessels were tied above and below, and the whole gland was completely excised. One or two distal filaments were accidentally ruptured, but the greater part of the nerve was preserved. Following the operation there was temporary facial paralysis, but in a couple of months the patient had twitchings at the angle of the mouth and kinesthetic sensations. In about four months she had some movement of the facial muscles about the eye and mouth. A year afterwards she had good control of the facial muscles of that side, with very occasional slight twitchings. At this time very little inequality in the movements of the two sides of the face was discernible and the extent to which the patient could move the facial muscles of the side of the operation is depicted in the accompanying reproduction of a photograph which was taken during the phase of contracture. The operation requires the expenditure of considerable time and care but the cosmetic results repay the trouble. The question is of importance because there is no possibility of performing any kind of nerve anastomosis after injury to ramifications of the facial nerve passing through the parotid gland.

Certain Fatal Forms of Pharyngeal Diphtheria.—Summaries of eight cases are given by A. Harris. He says that in certain cases a fatal prognosis can with certainty be given. These cases are characterized by a grayish facies with anxious expression, vomiting (independent of food) of yellow or greenish matter; the vomiting like that of cerebral trouble, severe abdominal pain, albuminuria, but no casts and alteration in the rhythm of the heart sounds. This appears after the vomiting has set in. One of the heart sounds is often reduplicated. The patients are generally very restless but remain conscious to the end. The membrane in this group of cases is dark-colored and the breath is most offensive. Cultures in such cases show large numbers of staphylococci and streptococci mixed with the Loeffler-bacillus. Antitoxin is here useless.

Treatment of Rheumatoid Arthritis.—W. I. Midelton commends the use of blister counter-irritation applied in the regions of the cervical and lumbar enlargements and gives the notes of five cases out of a series of twenty. His results have been better than from other methods. Several of his cases were extremely feeble, but no ill-results followed the applications. In one instance a patient much subject to dysuria had some strangury, but it was temporary and yielded to copious drinking of water and the internal use of hyoscyamus. This therapy was some time ago recommended by Latham, who believes that the lesions in the joints are the results of irritative and destructive conditions in the regions of the cord named. The author is not altogether in accord with this view as he regards the disease as due in some measure to a cerebrospinal toxemia. Latham based his views on the fact that first clinical experience has taught that injuries to the spinal cord or even to the nerves of a limb will set up arthritic changes which cannot readily be distinguished from those seen in the earlier stages of rheumatoid arthritis. And second that pathological facts appear to show that the trophic nerves of the bones and joints are found in the vaso-motor nerve trunk, and that they issue along with the motor fibers from the anterior cornua of the spinal cord. These fibers are, (1) the muscular trophic fibers, connected with a group of large caudate cells, and that it seems now generally admitted that both irritative and destroying lesions of the ganglion cells of the anterior horns of the spinal cord and their homologues in the medulla oblongata, nerves, and neurs, or of the efferent fibers which unite these cells with the periphery, may give rise to active atrophy of [illegible]

Clinical Journal, September 28, 1907.

Acute Streptococcal Septicemia Occurring at the Menstrual Period.—One case is reported by W. F. C. Dickson, whose patient was a girl of sixteen. Her illness was associated with tonsillitis at the time of her menstrual period. On the second day severe diarrhea and vomiting occurred with a sharp rise of temperature. The heart became rapid and irregular and a systolic apex murmur was audible. A tense diffuse swelling was found in the region of the left parotid, extending halfway down the neck and very tender on pressure. The fever continued and the patient gradually grew worse, dying on the evening of the fourth day. The provisional diagnosis was acute septicemia from the inflammation in the parotid gland as above described. Autopsy revealed a condition of general sepsis. Cultures were taken from the parotid cervical glands, left tonsil, Fallopian tubes, spleen, heart muscle, and femoral bone marrow. In every case pure cultures of *Bacillus coli* were found except in the bone marrow which yielded in addition a streptococcus. It was thought that the case was one of acute streptococcal septicemia, the presence of the *Bacillus coli* being probably a terminal phenomenon. Though the source of infection *may* have been the throat or intestine, the author is inclined to think that the condition of the uterus and Fallopian tubes pointed rather to these organs being the origin of the bacterial invasion, and that the case may be regarded as one of "menstrual septicemia," precisely analogous to puerperal septicemia, and due to infection occurring in a somewhat delicate girl during the menstrual period.

Primary Epithelioma of the Vagina, Showing Autoinoculation or Contact Infection.—A. J. Wilson's patient was a woman of forty-eight years complaining for three months of pruritus vulvæ. She had had twelve healthy children. Examination showed just at the left side of the introitus vaginæ, a small ulcerated swelling. On the other side more anterior and extending back into the vagina was a larger ulcerated patch with rough granular surface and raised edges. There was a slight offensive discharge. Inguinal glands were not enlarged and the urine was free from albumin and sugar. The growths were excised and seven months later there had been no recurrence. The excised masses proved to be squamous-celled epithelioma. Two theories were suggested to the double lesion. The first one (to which the author inclines) was that the lesion appearing the more recent was the result of an inoculation across the vulva. The other was that of the development of two epitheliomas in one vulva at the same time. The author adds some observations on the rarity of primary vulvar cancer and refers to reported cases of inoculations of the nature of the case described.

Berliner klinische Wochenschrift, September 23, 1907.

The Causative Agent in Trachoma.—Fermi and Repetto describe a series of investigations on the nature of the etiological agent in trachoma conducted with material obtained from fifty uncomplicated cases of the disease. It was found that on filtering the secretion from the infected eyes through a Berkfeld filter the infectious agent was removed, for no reaction could be obtained on inoculating with the filtrate the conjunctival mucous membrane of monkeys, of the authors themselves, and of ten other persons. As a control observation unfiltered secretion was applied to two healthy conjunctivæ with a positive result. Inoculations made with a mixture of all the organisms from the trachoma cases that could be grown agar were also consistently negative. The authors were also unable to detect any constant structure that might be considered the causative agent by the use of any staining methods, including that of Giemsa.

Münchener medizinische Wochenschrift, September 17 and 24, 1907.

A Simple Dressing After Amputation of the Breast and Other Operations Extending into the Axilla.—Ebner says that the customary method of fixing the arm close to the body after amputation of the breast has the drawback of interfering with the mobility of the shoulder joint and favoring contraction of the scar, which it takes a considerable length of time to overcome. Various incisions have been described with the object of avoiding this result, but a very great improvement is represented by a suggestion made by Lexer, and applied in modified form by the author. It consists in keeping the arm in the extended and abducted position from the first, and Ebner has found that the simplest way of accomplishing this is by slipping over the arm a sleeve of stockinet which at its distal end is tied by a strip of bandage to the head of the bed. The arm is kept at an obtuse angle to the body, or at least at a right angle. Instead of the usual cumbersome dressing involving the use of many bandages, the author applies only a comparatively small amount of gauze held in position by strips of adhesive plaster. According to this method, the patients are said to acquire complete function of the arm in a very short time, and photographs of two

patients are appended, showing both arms raised above the head on the seventh day after amputation of the breast.

Iodine Benzine Disinfection.—Enderlen speaks of a method of hand disinfection described by Heusner. The active agent employed has the following composition: Tincture of iodine, 10; benzine, 750; paraffin oil, 250. It is used by pouring half a pint into a dish and scrubbing the hands with it for five minutes. Preliminary washing with water is inadvisable. Enderlen has tried the method, and says that it is serviceable, though it is open to the objections that it discolors the hands, causes eczematous irritation of the skin on long-continued use, and damages rubber gloves. The results, as far as the wounds are concerned, seem to be a little less good than those obtained when the older methods of hand sterilization are used.

Bacteriological Examinations of Gallstones.—Bachmeister examined gallstones from twenty cases and comprising all the ordinary varieties. Of these sixteen were found to be sterile in the interior, while in four cases bacteria were found in the center. In three of these cases the organisms were colon bacilli, whereas in the fourth, that of a woman dying in the fourth week of typhoid fever, typhoid bacilli were found. The author is of the opinion that in all of these cases the stones were of long standing, and that the bacteria had not formed a nucleus for their formation, but that their presence was due to a secondary invasion of the calculus by the germs. The possibility of such an occurrence was proved by experiment.

Observations on Pirquet's Tuberculin Reaction.—Engel and Bauer have tested this form of the tuberculin reaction on forty-eight infants and two hundred and eighty older children. The test consists in performing a local inoculation with old tuberculin diluted four times. If the result is positive a red flat papule appears at the site of inoculation at the expiration of twenty-four to forty-eight hours. The originator of the reaction claimed for it absolute specificity, and commended it on account of its convenience and freedom from danger. The authors consider, however, that Pirquet's conclusions were founded on insufficient material, and, although they admit that there is an intimate relationship between the reaction and tuberculosis, they do not believe that a positive result is always indicative of the disease. Of the forty-eight infants tested, six gave a positive reaction, but five of these appeared from the clinical standpoint to be free from tuberculosis. At the autopsy on one of these no traces of tuberculosis could be discovered. The other four did not react to a subsequent injection of tuberculin. Of the 280 older children, whose ages ranged from three to fourteen years, a considerable percentage gave a positive reaction, and for these the authors believe that the test is more reliable. They conclude that the method is of value in making observations on the prevalence of tuberculosis in general, but that in cases presenting diagnostic difficulties it is not likely to prove of great service since its results are more difficult to interpret than those of the injection of tuberculin.

The Demonstration of Typhoid Bacilli in the Lice of Typhoid Patients.—Abe has repeated for the typhoid bacillus observations that have already been made in regard to the organism of bubonic plague. In four cases of typhoid fever it was possible to demonstrate the presence of typhoid bacilli in the bodies of lice taken from the clothing and persons of the patients. The insects were crushed in a mortar after having been washed in bichloride solution and sterile water. Cultures from the crushed bodies gave positive results and on injecting portions of the crushed bodies under the skin of mice the animals died of typhoid septicemia. In two instances in which fleas were taken from the persons of nurses caring for typhoid patients no bacilli could be found in the insects. The author concludes that vermin play an important part in the dissemination of various infectious diseases, especially of typhoid fever.

Ventilation by Means of the Action of the Wind.—Quincke describes a method of procuring ventilation which he has applied successfully for several years in hospital wards and which he considers would also be useful in restaurants, railway waiting rooms, etc. The plan is particularly applicable in winter when it is difficult to introduce fresh air without at the same time causing drafts. Two of the walls of the room, preferably on opposite sides, are pierced by pipes from four to eight inches in diameter which externally are flush with the surface of the building and internally are curved at right angles so that the opening points directly upward. These pipes are placed high up near the ceiling and if possible should be on the sides of the building facing the prevailing winds. The inner ends of the pipes are provided with dampers controlled by chains hanging down within easy reach. By means of this installation fresh air may enter freely at one side and through being deflected upward against the ceiling produces a current emerging at the opposite side of the room. As the cold air has a tendency to sink the entire air of the room is gradually replaced by fresh air without any danger of drafts. Several modifications of the plan are described by means of which air may be caused to enter the outside openings even though the wind is not blowing at right angles to the wall and to provide for cases in which the room does not have two external walls.

French and Italian Journals.

Gigli's Operation in Obstetric Practice.—Ballenghien reports two cases of pubiotomy in patients of the working class done in the homes of the patients. Premature labor is not to be considered in such cases, for the workingman has not the money nor the facilities to successfully bring up a premature infant. Embryotomy is not to be thought of, and the cesarean section belongs to the hospital and to severe contractions of the pelvis. By the use of pubiotomy many infants may be saved without danger to the mother. A firm osseous union may be obtained by using a firm bandage and rest in bed for four weeks. The author sees no advantage in the use of the subcutaneous section. He advises a section obliquely from above downward, to pass outside the subpubic tubercle; it should not be made too near the symphysis in order to avoid the bladder and corpus cavernosum of the clitoris.—*Journal des Sciences Médicales de Lille*, June 1 and 8, 1907.

Cancer of the Uterus.—O. Laurent describes cancer of the uterus as latent or insidious, and characterized by the triad of symptoms: pain, leucorrhea, and hemorrhage. It may spread to the vagina, adnexa, parametrium, bladder, rectum, ureters, peritoneum, and by metasasis to the heart and other internal organs. In two-thirds of all the cases it is of the cervix, and it may involve the body by extension, or may be primary in the body. The parametrium and lymphatic glands may be involved early or very late. Cancer of the body is much slower and less malignant than that of the cervix. When involving the cervix it may be pavement, cylindrical, or atypical epithelioma, but when of the body it is always cylindrical. It may be nodular, papillary, or excavating. It may be distinguished from chronic metritis by its more granular and glistening appearance; from benign papilloma by the absence of cauliflower growths; from fibroma or polypus of the cervix by the absence of the ring of the cervix surrounding it.—*La Revue Médico-Sociale*, June 10, 1907.

Experiments in General Treatment by Antidiphtheritic Serum.—Mongour has treated a number of general diseases by injections of antidiphtheritic serum with success. He has found it especially useful in anginas not of diphtheritic origin. In these the false membranes soon fall off and health rapidly returns. Arthralgia and eruptions may be produced. Cure is so rapid that a convalescent period is absent. It has been used with success in four cases of typhoid fever, one of septicemia, three of pneumonia, three of pulmonary abscess, two of scarlatina, one of pseudomeningitis, and one of cholecystitis. These cases were treated by the serum alone. The modifications were so rapid and the lowering of temperature so manifest after each injection that the author feels sure of the good effects of the remedy. The method of action is probably by the effect on the leucocytes. Is this hyperleucocytosis due to antibodies present in the serum or to alexins circulating in the normal serum? The author is not able to decide this point.—*Journal de Médecine de Bordeaux*, June 30, 1907.

Primary Infections of the Tonsils, Palate, Testicle, and Articulations in Tuberculosis.—G. Ghedini has injected tubercle bacilli directly into various structures to ascertain the method of spread of the tuberculin infection. In primary tuberculous affections of the tonsils and other parts of the oral cavity the infection spreads to the vessels, cervical lymphatic glands, superficial and deep of the clavicular region, mediastinal and bronchial glands, and the apex and center of the lungs. In most cases the infection is limited to these organs, but occasionally a general miliary tuberculosis sets in. Generally the process follows the lymphatics. In some cases the germs follow the vessels instead. Injected into the testicles they follow the afferent spermatic lymphatics, the lumboaortic lymphatics, and then reach the ganglia of the peritoneal serosa both parietal and visceral. Injected into the articulations the usual inflammatory reaction takes place, invading the serous membranes, articular ligaments, periarticular connective tissue and muscles, and the neighboring lymphatic glands. The tubercle bacilli prefer the path of least resistance.—*Annali dell' Istituto Maragliano*, Vol. 2, Part li.

Book Reviews.

The Abdominal and Pelvic Brain, With Automatic Visceral Ganglia. By Byron Robinson, B.S., M.D., Chicago, Ill. Author of "Practical Intestinal Surgery," "Life Size Chart of the Sympathetic Nerve," "The Peritoneum, Its Histology and Physiology," etc. Professor of Gynecology and Abdominal Surgery in the Illinois Medical College; Consulting Surgeon to the Mary Thompson Hospital for Women and Children, and the Woman's Hospital of Chicago. Hammond, Ind.: Frank S. Betz.

In this volume will be found a number of papers, embodying the author's studies on the anatomy, physiology and pathology of the abdominal and pelvic brain. The abdominal brain is the solar or epigastric plexus; and the pelvic brain is the cervicouterine ganglion situated on each side of the uterus. The book is practically a treatise on the abdominal sympathetic nerves, with special attention to the needs of the surgeon and physician; most of the chapters have been published in various medical journals during the past fifteen years. In several respects the present work is unique. It represents much original work on the part of the author; at the same time ample acknowledgment is made to previous workers in the same or neighboring fields; the author has struck out new paths for himself, and has probably done more work on the sympathetic system than any other writer; the illustrations are original, and represent many actual dissections, and not one of them contains a single feature calculated to appeal to the eye rather than to the brain. The book will make its way on its own intrinsic merits, and they are many. Among the most serviceable of the chapters may be mentioned those dealing with splanchnoptosis and visceral drainage. To the student and thinker the book will be indispensable; but it is a pity that so valuable a book is so poorly printed and edited.

L'Amnésie au Point de Vue Semeiologique et Médico-Légale. Par les Drs. G. Dromard et J. Levassort. Ouvrage couronne par l'Académie de Médecine (Prix Lorquet, 1906). Paris: Felix Alcan, 1907.

Studies of memory from psychological and from pathological points of view have been previously attempted; but this is the first work which we have seen which bears chiefly on the medico-legal aspect. The authors have reviewed the unfinished work of Dr. Garnier and acknowledge their assistance and inspiration from this source. They have divided the amnesias into functional and organic. Among the functional they include amnesia from shock and from alcoholic and other intoxications, and amnesia in certain of the neuroses and insanities. The organic varieties are those which follow local or disseminated lesions of the brain. There is a discussion of amnesic and paramnesic illusions, and of so-called progressive dysamnesias; while the last part of the book is devoted to a consideration of amnesia in its relation to legal medicine. In this section those forms occurring in epilepsy, early paresis, hysteria, alcoholism, and cerebral traumatism, and the simulation of amnesia, in legal medicine, are particularly considered, and illustrated by carefully described cases. The book will be found of special interest and value to the medicolegal expert.

Modern Surgery, General and Operative. By John Chalmers Da Costa, M.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital, and Consulting Surgeon to St. Joseph's Hospital, Philadelphia. Fifth Edition, Thoroughly Revised and Enlarged, with 872 Illustrations, Some of them in Colors. Philadelphia and London: W. B. Saunders Company, 1907.

From the appearance of the first edition of this work thirteen years ago, it has taken rank as one of the best of the single volume surgical treatises in the English language, and so long as the revision continues to be made with the care and thoroughness which characterize this fifth edition it stands in no danger of being outclassed by any of its contemporaries. In addition to a number of corrections and expansions in various sections, a quantity of new matter has been introduced. The added matter includes descriptions of Brophy's operation for cleft palate, Willy Meyer's operation for mammary cancer, Murphy's and Hugnier's operations for ankylosis, Cushing's operation for intracranial hemorrhage of the newborn, Matas' operation for aneurysm, scopolamine morphine anesthesia (of which the author expresses his fear, although he admits its efficacy), White's treatment of whitlow, typhoid cholecystitis, and much more. A few additional illustrations have also been inserted. In the section on segregation of the urine too much prominence has been given to the uncertain method of Harris and no mention is made of the superior methods of Luys and Cathelin, which are nearly as certain as ureteral catheterization and far more safe. The book is open to minor criticism on other points also, but its excellencies far outweigh its defects.

Materia Medica, Therapeutics, Pharmacology, and Pharmacognosy, Including Medical Pharmacy, Prescription Writing, and Medical Latin. A Manual for Students and Practitioners. By William Schleif, Ph.G., M.D., Demonstrator of Medical Pharmacy in the Medical Department of the University of Pennsylvania. Series Edited by Bern B. Gallaudet, M.D. Third Edition, Revised and Enlarged. Philadelphia and New York: Lea Brothers & Co.

In this third edition the entire text has been revised and adapted to the new Pharmacopœia, metric equivalents have been introduced, the chapters on the administration of drugs have been enlarged, some new drugs have been added, and the volume is increased by nearly one hundred pages. The book will be useful to the medical student and also to the practitioner; the latter will particularly appreciate the index of diseases and remedies. In another edition the two prescriptions containing fluid extracts, on page 41, should be corrected.

On Fermentation. By Alonzo Englebert Taylor. University of California Publications; Pathology. Berkeley: The University Press, 1907.

This publication comprises, in a condensed form, some lectures delivered in the University of California, in October, 1904. The subject is considered from the point of view of general chemistry and chemical biology; and the reader with a fair knowledge of chemistry will find here a good résumé of what is known of the various fermentations of importance in the animal economy. A useful bibliography is appended to the several sections. There are numerous misprints in the volume, and the spelling is occasionally antiquated, *e.g.*, æthyl, æther.

Traitement Chirurgical du Cancer du Colon. Par le Dr. Joseph Okinczyc. Prosecteur à la Faculté de Médecine. Ancien Interne Lauréat des Hôpitaux, etc. Paris: Steinheil, 1907.

In this unusually complete and painstaking study of cancer of the colon may be found the statistics of fifty-eight cases, and a consideration of the diagnosis and surgical treatment of tumors. Special attention is given to colectomy in one stage. The work bears the stamp of great devotion and close application and is undoubtedly an important contribution to the subject.

Modern Methods of Diagnosis in Urinary Surgery. By Edward Deanesly, M.D., B.Sc. Lond., F.R.C.S., Hon. Surgeon Wolverhampton and Staffordshire General Hospital. London: H. K. Lewis, 1907.

Although this little volume contains nothing which is not familiar to the genitourinary specialist, it will be of service to the general practitioner in helping him to arrive at a diagnosis when some of the older clinical methods fail him. The author thinks that historical tradition is too often a hindrance to the advancement of surgical science, and that "even the most recent textbooks of general surgery rarely reflect the best practice of the day among good surgeons. Often their teaching is ludicrously inadequate, and any student who gives modern replies to ancient questions runs the risk of being rejected by his examiners." The volume is carefully written, instructive, and very readable.

Étude Expérimentale de la Pleurésie Sero-Fibrineuse Tuberculeuse. Par M. le Docteur P. Cartier. Paris: Steinheil, 1907.

This little monograph is divided into three parts: The first deals with the history of experimental tuberculous pleurisy; the second with a criticism of methods employed by other investigators; the third with original work. The virulence of a pleuritic effusion was studied in a twofold way: by inoculations into guinea pigs and by a study of the histochemistry of the fluid itself. The virulence was estimated from the dose required to infect a guinea pig; from the form of the resulting lesions, and the length of time the animal survived the inoculation. There was no relation between the number of bacilli found in the exudate and the virulence of the fluid. By counting the cells in the fluid, however, it was found that the poorer the latter was in red and white corpuscles the more virulent was the liquid.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twentieth Annual Meeting, Held at Detroit, Mich., September 17, 18 and 19, 1907.

DR. ROBERT T. MORRIS OF NEW YORK, PRESIDENT, IN THE CHAIR.

Observations and Reflections on the Etiology of Gall-stone Diseases.—Dr. HUGO O. PANTZER of Indianapolis, Ind., said that the study of the clinical significance of gall-bladder pathology to-day stood in the medical foreground. Recent developments had shown that the gall-badder was second only to the appendix among the abdominal organs in its disposition to take on disease. Like the appendix, the gall-bladder was found to be a catchpool of disease germs, which displayed their activity under signs which for a long time went unrecognized or were incorrectly interpreted. The view of Kehr that an infection supervenes upon preexisting gallstones was supported by clinical and pathological observations and reasoning. It would seem indisputable pertaining to cases attended with rise of temperature; but less so where pyretic temperatures were wanting. There were, no doubt, cases where the verified passage of stones was unattended with fever. The writer about twenty years ago systematically treated attacks of recurrent gall-stone colic with podophyllin. This remedy was given in ¼-grain doses, three times daily, with just enough morphine and ipecac to touch off the harsh edge of the intestinal colic produced by it. It was found that this remedy in the majority of cases brought on biliary colic of variable degree. It was not equally successful in eliminating stones, because of the nature of the accompanying conditions in such cases and the varying size of gallstones. But a number of the cases so treated were relieved of gallstones, which appeared in the stools. One such case the author reported in detail. A gallstone engaged at the neck of the gall-bladder might excite an irritation of the wall of this organ not unlike that observed in the pregnant uterus when its contents become unsettled, and these acted like a foreign body. The vaginal portion suddenly swelled to a large size, with edematous infiltration, and the dormant uterine musculature became active; rapid dilatation of the cervical canal and violent expulsive pains occurred. In the case of the gall-bladder, a stone wedged in its cervical canal might be supposed to bring forth similar changes, affecting both the musculature and connective tissue of the entire organ. Opinions of authors and practitioners varied greatly as to what size of stones could be passed by the cystic or common duct. No doubt most times large stones that were passed by the bowel or vomited had left the gall-bladder through unnatural openings; yet there was unmistakable evidence of comparatively large stones having passed by natural ways. The temperature should be regularly taken in all cases of gallstone colic. Its elevation in a case of gallstone colic might be the first definite sign of a grave disease. Every case of biliary colic having temperature demanded a local examination to detect evidence of an inflammatory character, gangrene, and pericystic involvement, or excessive enlargement. The persistent absence of fever would commonly indicate a non-dangerous condition, and when associated with concurrent conditions might warrant persistence in non-surgical measures.

Dr. JOHN A. LYONS of Chicago related the case of a physician whom he saw about four months ago. Blood tests were made to determine whether the case was one of cholecystitis or appendicitis. The pain radiated from the right to the left hypochondriac region. These blood tests were made by men of eminence. It was decided that the case was one of cholecystitis, and a noted surgeon concurred in the diagnosis and operated. Operation disclosed multiple carcinoma of the liver. This case was cited to show that it was difficult for even eminent practitioners to make a positive differential diagnosis between gall-bladder disease and appendicitis in some cases.

Dr. JAMES F. W. ROSS of Toronto referred to five cases of gangrene of the gall-bladder he had had. Whenever this condition was diagnosed it required immediate operation, just as a case of gangrene of the appendix did. In one case no gallstones were present, yet gangrene of the gall-bladder had taken place. This case demonstrated to him the possibility of gangrene of the gall-bladder without the presence of stones.

Dr. JAMES F. BALDWIN of Columbus, O., said he had had a number of cases of gangrene of the gall-bladder, and intended some time to make them the basis of a paper on this subject. He had noticed a symptom to which Dr. Ross had called attention—namely, irregularity of the pulse. The last patient upon whom he operated had no elevation of temperature or acceleration of pulse, but severe pain. The patient gave a history, going back one year, of attacks of pain, and a Cincinnati physician who saw him in one of these attacks thought it was clearly the appendix that was at fault. The man was in a desperate condition, so that an immediate operation was clearly indicated. Dr. Baldwin operated, going high up, as he thought there was more tenderness over the gall-bladder than over the appendix, and he struck it just right. The gall-bladder was gangrenous; it had ruptured, and contained fifty gallstones. The patient recovered.

Dr. JOSEPH PRICE of Philadelphia said that gallstone disease was exceedingly common. In insane asylums it was found that fully 30 or 40 per cent. of the inmates had gallstones, as demonstrated by post-mortem examinations, without symptoms. At the female department of the Norristown Asylum, of 1,200 women, who rarely had symptoms of gallstones, gallstones were found in 30 per cent. of the cases that came to post mortem. The physicians in this institution were good diagnosticians; they had found concealed hernias; they had recognized appendicitis in these demented women, which was really a difficult thing to do. Dr. Price had not found gallstone colic a common symptom.

Dr. WILLIAM H. HUMISTON of Cleveland, O., referred to the frequency of gallstones without symptoms. During his residence in Vienna, for several months, he was in the habit of going to the autopsy room, where they had from six to twelve bodies daily. In a hospital with 3,500 beds, the frequency of gallstones was apparent, although the patients were thought to have died from other symptoms or other diseases without any symptoms of gallstone colic whatever; yet gallstones were found at the autopsies. On careful examination, he had found that a rigid right rectus was an indication of gall-bladder disease.

Dr. CHARLES L. BONIFIELD of Cincinnati said that physicians, in writing and speaking of gallstone colic, confused the conditions that really existed. There was a decided difference between a pain due to an acute inflamed and distended gall-bladder and one that was due to true gallstone colic. Gallstone colic was always due, in his opinion, to contraction of the gall-bladder, and this contraction might be caused by the effort of the stone to pass through the duct, or it might be caused by an inflamed condition producing contraction. It had been his experience that the cases that gave rise to gallstone colic frequently had small gall-bladders, without much fluid in them, and doubtless filled with stones, usually attended with some inflammation; and the small stones were apt to get into the gall-bladder. He believed that almost every patient who had gallstones was liable to develop symptoms. The presence of gallstones in some way predisposed to infection of the gall-bladder.

Dr. Pantzer, in closing, said the frequency of gallstones bore no relation to the frequency of gall-bladder disease. The figures of Riedel go to show that of 2,000,000 Germans only 100,000 were afflicted with troubles that were characteristic and came to the recognition of surgeons. The possibility of a cholecystitis gangrenosa was to be

entertained in every case presenting symptoms of grave inflammatory disease.

Tuberculosis of the Kidney, with a Report of Cases.—Dr. Rufus B. Hall of Cincinnati said that less than a decade ago the opinions of the foremost men in the profession were at variance as to whether tuberculosis of the kidney justified more than a tentative operation. They agreed that if a large accumulation of pus was present drainage was at least justifiable. It was the general consensus of opinion in the profession to-day that renal tuberculosis was a local affection, limited to only one kidney in the vast majority of cases. As to the method of infection, we must consider the circulation, the lymphatics, and extension from the bladder, as well as direct communication from the tuberculous focus situated near or outside the genitourinary tract. There could be little doubt but that the kidney was often affected without either the ureter or bladder being involved. It was also capable of demonstration that if the disease was far advanced in the kidney, the ureter rarely escaped infection. While the difficulties of diagnosis were many and complex, careful clinical study and the refinements of the diagnosis of the present day ought to reward practitioners in a correct diagnosis in a large majority of cases even early in the disease. He placed much weight upon the importance of an early diagnosis, and said that it was perfectly possible to make it in the vast majority of cases. If a diagnosis could be made early and the kidney abscess drained, many of the cases could be cured without the sacrifice of the kidney, which necessarily followed if the disease was allowed to progress many months. If the general profession would realize the importance of considering tuberculous disease of the kidney as one of the chief causes of irritable bladder, occurring in patients between the ages of 20 and 50 years, where some other good cause could not be easily located to account for their condition, especially if the urine contained pus, and the urine was acid, there would be a great advancement made toward an early diagnosis of this grave condition.

Dr. Edward J. Ill of Newark, N. J., said the first case of tuberculosis of the kidney he saw dated back eighteen years. The patient was a girl, who had tuberculosis of the left kidney and ureter. The case was seen in the days before operations were undertaken for the relief of this condition. This patient did not undergo an operation, but was perfectly well to-day. No tubercle bacilli could be found in the urine. Another patient, seen twelve years ago, was perfectly well to-day. He did not cite these cases for the purpose of saying that they should not be operated on, but rather the reverse. In the last five or six years he had operated on six such cases, removing the kidney and ureter. All of the patients were alive, except two. One died of sepsis at the time of the operation, while the other died of lung trouble which previously was not recognized.

Dr. H. O. Walker of Detroit agreed with the essayist as to drainage of the kidney in tuberculous lesions. He had had some successful results by so doing.

Dr. O. H. Elbrecht of St. Louis cited two cases he had had of tuberculosis of the kidney, one of which he drained, and one he did not drain. One of his patients died from miliary tuberculosis eight weeks after the operation. The kidney was large, full of pus, and was drained. This was a case in which the kidney could not be removed without the pus coming in contact with the wound. In the other case the abscesses were small, and nephrectomy was done, without puncturing the various abscesses to find out what they were. He also removed the ureter in this case, and closed the wound. The patient recovered from the operation, but later died of miliary tuberculosis.

Dr. Joseph Price said that when a kidney was honeycombed with tuberculous lesions it was perfect folly to attempt drainage. Such kidneys should be removed. Undoubtedly there were many cases in which surgeons anchored so called floating kidneys which were really pathological. He cited such cases.

Dr. James F. W. Ross of Toronto said it was unpleasant to do a nephrotomy in these cases, and then find out afterwards that one had to do a nephrectomy. It was not an easy matter to say whether a surgeon should do a nephrotomy or a nephrectomy primarily. English authorities some years ago announced the dictum that nephrotomy should be instituted first, and that nephrectomy should be regarded as a secondary operation in cases of kidney tuberculosis. In these cases he had followed that out to some extent, because he had not been able to satisfy himself as to the condition of the other kidney. It was stated that tuberculosis of the kidney was generally bilateral, but in his experience that was not so.

Dr. James F. Baldwin emphasized the point that nocturnal frequency of urination was not only equal to the frequency of urination during the day, but was increased. He had noticed this in so many cases that he attached a great deal of importance to it. Where there was an irritable bladder, the erect position produced more congestion, and there was increased frequency of urination during the day, without relief at night. A patient noticed that he had to urinate more frequently at night than during the day, and later examination in these cases had verified a suspicion of tuberculosis. He had practised nephrotomy in two or three desperate cases, believing that nephrectomy would have turned the tide in these and the patient would have died.

Dr. Hall, in closing, said that if there were many abscesses, with different pockets, he invariably took the tuberculous kidney out. In a few cases the condition of the patient had been so desperate that he had simply drained, but had to remove the kidney in these cases months afterwards.

Toxemia of Pregnancy as Observed by the Gynecologist.—Dr. Raleigh R. Huggins of Pittsburg stated that observations led to the belief that pernicious vomiting, acute yellow atrophy, and eclampsia were but the results of conditions which, as a rule, had gradually developed. The onset might be severe enough to seriously impair the process of metabolism, and thus render the patient susceptible to many other complications which frequently accompanied pregnancy and the puerperium. That many dangerous complications were liable to develop after delivery as a result of previous toxemic conditions was a fact that had not received the attention which its importance merited. That there was much greater danger of infection at delivery, as a result of lowered resistance, than when the eliminative organs had been functionating normally throughout pregnancy. That in a number of cases of cholecystitis occurring during pregnancy and the puerperium, it had developed in the presence of toxemic symptoms, and that complications such as cholecystitis and empyema of the gall-bladder had been the direct result of an overworked liver, caused by the toxins of pregnancy. That a large percentage of cases of insanity occurring during the puerperium gave a history of toxemic symptoms previous to delivery.

Dr. E. Gustav Zinke of Cincinnati said that a woman who became pregnant little knew the dangers that might beset her path during the following nine months. Few consulted a physician in time, and even when some physicians were consulted in time they did not give the cases the necessary attention. He was satisfied from what he knew about puerperal toxemia that probably it would be eliminated in nine-tenths of the cases if the physician knew all about it, and if patients were instructed to consult physicians who would do as they should by them. These women should have the necessary care from the beginning of their pregnancy until the end of it, until they were able to be up and about after their confinement. This was what should be taught young practitioners; this was what practitioners should preach to the public.

Dr. Joseph Price referred to a young woman who developed diabetes during pregnancy, and the question arose as to whether it was safe for her to bear a child. He

was called to determine that point. He believed that the woman could safely go on to term. She was watched with great care by a good physician, a man of great skill, who made high application of the forceps, and delivered her of a fine child who was now alive and a member of an influential family.

Dr. JOHN A. LYONS recalled two or three cases of puerperal sepsis in his experience, but not one of them came to him in time to do much good.

Dr. O. H. ELBRECHT was glad that the author had directed special attention to the liver in these cases, as he believed this was the place to look for the etiology. He reported cases of hyperemesis gravidarum. In one case it was necessary to resort to the induction of abortion to stop the vomiting.

Dr. WILLIAM H. HUMISTON said that in the severe cases that had resisted other methods of treatment, he had had good success from the use of stomach lavage, twice daily, with rest in bed, and with enemas of saline solution.

Treatment of Puerperal Sapremia and Puerperal Sepsis.—Dr. JOHN E. CANNADAY of Hansford, W. Va., outlined the present status of treatment of these conditions. He said that the treatment of the former had been definitely settled. The treatment of puerperal sepsis, however, was undecided, unsettled, and unsatisfactory. There were few conditions in which the treatment was farther from ideal than this. There were several more or less ineffective methods of treatment. Each had its champions. The yeasts, nucleins, sera, and more recently the opsonins had been lauded from time to time. In one or several of these evidently lay the hope of the future. The use of the curette had been praised by a few and decried by many. Pryor's iodoform gauze method gave good results in the hands of a few. Several of the more radical men practised hysterectomy, but there was danger of a deadly staphylococcus infection external to the uterus. The author advocated vaginal and uterine douches of a physiological salt solution, supplemented by cul-de-sac drainage, whenever there were any evidences of infiltration or of abscess posterior to the uterus, in the broad ligaments, or in the tubes. Saline transfusions, frequently administered, nutritious diet, and other general supportive measures should be resorted to.

End Results in Operations for Prolapsus Uteri.—Dr. JOHN W. KEEFE of Providence, R. I., expressed the conviction that hysterectomy for prolapsus should be practised in only rare instances, as it was an operation attended with a high mortality. The loss of the uterus had a depressing mental influence upon many women, and at the child-bearing age should never be performed for prolapsus uteri. Simple procedures, like the Alexander operation, amputation of the cervix, anterior and posterior colporrhaphy and perineorrhaphy, attended with no mortality, were sufficient, not only to relieve the symptoms, but to enable the patients to bear children and subsequently to having borne children to have the uterus in good position with no symptoms. The author tabulated 48 cases of operation for prolapsus uteri of varying degree. Of this number 46 women were treated by the combined methods of plastic operation on the parturient canal and the Alexander operation. He had been able to trace after operation 23 cases out of the 48. Of the 23 patients examined he had found 18, or 77 per cent., with the uterus in good position and cured of their previous symptoms. Of the 5 remaining, 2 had a return of prolapsus to the second degree, but without any subjective symptoms. One was treated by plastic work on the vagina, and for four years remained well until she gave birth to a child, after which the prolapsus returned. In this case no Alexander operation was done. Another woman was also treated by plastic work, also with a resulting failure. This case returned later, the plastic work was repeated, and an Alexander operation done. After this the patient bore two children, and on examination, August 21, 1907, the uterus was found in good position, with a moderate cystocele and rectocele. The patient had had no return of the symptoms for which she sought operation. The other case of failure was advised to return for hysterectomy. Seven women had borne children since operation, and one was pregnant at the time of examination. The labor in every case was normal, free from the use of forceps, and did not cause a return of the prolapsus except in one case, which did not have the benefit of an Alexander operation. The author was convinced of the practical value of the Alexander operation combined with plastic surgery upon the uterus and vagina in cases of prolapsus uteri.

Common Mistakes in Gynecological Diagnosis.—Dr. W. S. SMITH of Baltimore, who contributed a paper on this subject, referred to easy and difficult cases. The most skilful specialists found it impossible to avoid mistakes in obscure cases. The general practitioner should make them less frequently in common and easily recognized conditions. Elements of diagnosis were often overlooked; histories were disregarded; examinations were careless, and conclusions reached too hastily. He referred to the routine methods of treatment without any diagnosis, and made a plea for more orderly, deliberate and systematic investigation.

Phlebitis Following Abdominal Operations.—Dr. ORANGE G. PFAFF of Indianapolis presented the following conclusions in a paper on this subject: "1. Many of these cases are simply extensive aseptic blood clots, without any true inflammation. 2. There must be present an abnormal plasticity of the blood in order that thrombosis may be the result of surgical traumatism. 3. The clot generally receives a mild form of infection introduced into the wound at the time of the operation, and in turn an invasion of the vein wall results. 4. As stagnation is such an important element in the etiology, getting patients up earlier will undoubtedly reduce the liability to thrombosis. 5. As an abnormally high degree of plasticity of the blood is essential in developing the disorder, the blood ought to be tested by some recognized standard in every case, and if found in a dangerous state, operation should be postponed until medication shall have brought it back to a normal condition.

Dr. HERMAN E. HAYD of Buffalo said there was undoubtedly great susceptibility on the part of some women and men to phlebitis, or it would not be so common after the most trivial operation or undertaking. A woman patient was at present in bed with a post-operative phlebitis, he having operated on her four weeks ago for a simple recurrent attack of appendicitis. The wound healed kindly, without any evidence of irritation or pus. The patient was married and sterile. She was anxious to have children. He found the tubes and ovaries healthy. There was no history of gonorrhea either on the part of the husband or the wife. He dilated the cervix, put in an intrauterine stem, and the vaginal work was done with just as much care as the work above. The stem was thoroughly boiled before its insertion. There was no question as to the possibility of an infection, so far as it was evident to him. He did a curettage before operating on the appendix, so that his hands were perfectly sterile for both operations, because he had no evidence of trouble from the latter. He used gloves for the vaginal work, and the same pair of gloves for the abdominal. The woman left the hospital in two weeks, and was able to walk upstairs to her apartment. The next day she complained of pain in the calf of the leg. He was suspicious of phlebitis. A couple of days afterwards the left leg was two and a half inches larger than the right. He had no doubt that the phlebitis came from the vaginal work, and not from the appendical. It is possible, however, it might have come from the latter. He cited this case to show that after such trivial undertakings under the most careful precautions phlebitis was likely to follow, and probably this woman would be in bed five or six or eight weeks.

Dr. Joseph Price said that wherever much acrobatic surgery was done, phlebitis would follow operation. He had noticed with anxiety that in certain institutions where great prominence had been given to binders, crutches, and retractors, phlebitis followed the operations. In one institution they had had forty-eight cases of phlebitis following operations, twenty-five of ileus, and eighteen of ether pneumonia. One would expect such a record from the rough handling of the tissues by instruments. Personally, he had not had a case of phlebitis following operation for five or ten years. Really, he did not know what it was, and it pained him to hear men talking about the early getting up of patients, which was now so commonly advised. The too early getting up of patients after operations was a variety of criminal assault on them. Phlebitis was comparatively common in some hospitals, while very rare in others.

Dr. Robert T. Morris of New York had had two cases of phlebitis on the left side after operation on the appendix. He found it difficult to explain the occurrence of left-sided phlebitis in these two cases.

Dr. Hayd said in his case the phlebitis was left-sided.

Dr. James F. Baldwin asked if the members had not seen phlebitis in cases of appendicitis in which no operation had been made?

Dr. Morris replied that he had seen it in cases in which there was no infection. There was none in either of the two cases he had mentioned.

Dr. John W. Keefe of Providence, R. I., cited a case of hernia in a woman in whom he did a Bassini operation. The operation was absolutely clean; it was done in fifteen minutes, but a left-sided phlebitis occurred, and within two weeks a right-sided phlebitis followed. At no time was there any suppuration or redness about the hernial wound.

Dr. Edward J. Ill said that for a number of years he had no cases of phlebitis, and then came eight in succession. These cases were operated on, both in hospitals and in private practice. Not one of his assistants had had a phlebitis following operation, but he had them all. He believed it was a septic condition, for he had seen it follow as much as five weeks after a simple appendectomy. What the nature of it was he hoped to learn some time; at present we did not know. He hoped that the peculiar condition of the blood which had been referred to by the reader of the paper would help us out. However, he thought surgeons should look to themselves. Any one who had seen Dr. Price operate could readily understand why he had not had any case of phlebitis in ten years, as his assault upon a patient was the gentlest or mildest possible. All surgeons could not treat patients in that way.

Dr. Hugo O. Pantzer commended the paper for its clear and convincing arguments. He felt that an exception should be taken to the early rising of patients after infectious disease. Most cases of phlebitis were aggravated as soon as the patients got up. In some instances phlebitis did not develop until the patient began to sit up.

Dr. Pfaff, in closing, was surprised that Dr. Price had not had a case of phlebitis in ten years. He thought certain factors in the etiology were going to be cleared up; that Wright was too good a man to be considered lightly in any statement he might make. Traumatism was inevitable in all surgical operations. Sepsis was also inevitable, but it was not always the septic cases that gave us phlebitis. It was the simple, easy cases, where clean, aseptic operations had been done.

Formation of an Artificial Vagina by Intestinal Transplantation.—Dr. James F. Baldwin of Columbus read a paper in which he described a new method for making an artificial vagina, and reported a case. He first described the method on theoretical grounds three years ago in the *Annals of Surgery*, but no case had then presented itself for operation. The operation consisted in making the usual opening between the rectum and bladder, and then lining this with a loop of intestine taken from the sigmoid flexure of the colon, or from the lower end of the ileum as seemed preferable. Continuity of the bowel was restored by an anastomosis, and the cervix, if the uterus was to be saved, attached to the bowel so that menstruation would take place through the artificial channel. In the case which he reported the operation was in every way successful, a capacious vagina lined with mucous membrane having resulted, with no tendency to cicatricial contraction.

Painful Menstruation in Young Unmarried Women.—Dr. W. A. B. Sellman of Baltimore discussed some of the causes of this condition. He considered the anatomical conditions existing, and said the cause of painful menstruation must be thoroughly understood before any attempt was made to relieve the condition. Painful menstruation was too lightly considered by the family physician, and it was not dealt with as a pathological condition. Any cause that would bring about a thickening of the lining of the uterus would eventually produce dysmenorrhea. Contracting cold during the menstrual flow, thereby interfering with involution of the uterus and the consummation of those changes which normally occurred in the tissues at this period, was a cause of painful menstruation. Shock and mental influences were strong factors in bringing about this condition. An imperfectly developed condition of some portion of the sexual organs, any abnormality in development, any vicarious function which might prevail in any of them, would be a cause for painful menstruation. After enumerating other causes and the part played by other conditions in producing dysmenorrhea, the author pointed out that these suffering young women should receive the benefit of those operations which had been so successful in giving permanent relief to this class of cases. A girl suffering from dysmenorrhea was an invalid. She was unable to meet her friends and engage in those entertainments and diversions in which she was expected to take part. The cervices of these suffering young women should be dilated or slit, curettage performed, or something else done to bring an end to their pain.

Dr. Bertha van Hoosen of Chicago said that one of the most potent causes of painful menstruation was a chronic appendicitis, or at least a diseased appendix, which made itself known only at the time of the menstrual period. During the past two years she had recognized more and more the importance of making a thorough examination of the appendix, and since she had done this she had had almost no case of dysmenorrhea that she had not been able to relieve.

Dr. Joseph Price said that the prominence given to dysmenorrhea and menstrual disturbances generally was too great. He believed that early marriage was the best treatment for all varieties of dysmenorrhea, except in those cases in which pathological conditions existed. Recently he had removed two small dermoids from women who had married and conceived. Twice the dermoids complicated their menstrual history. These dermoids should have been removed before the women were married, because these growths were prone to set up inflammatory action and cause adhesions.

Dr. J. Henry Carstens of Detroit said that many of these young women, after they married and bore children, had no further disturbances of menstruation. When the trouble was in the uterus, he had repeatedly called attention to the value of the stem pessary to remove the hypertrophied condition of the mucous membrane. In several cases in which the dysmenorrhea was due to an undeveloped uterus, when the uterus could be stimulated to development good results could be obtained in those that had resisted other forms of treatment. In another class of cases there was pelvic inflammation, the result of some tubal infection. This might be due to tuberculosis or to some inflammatory condition of the appendix. In some cases of this class the surgeon was justified in making an abdominal section for either diagnostic or curative pur-

poses, and in nearly all of them one would find sufficient trouble to account for their distress, and would have very little or no difficulty in relieving the condition.

Dr. Hugo O. Pantzer emphasized the importance of the hygienic treatment in these cases. When young girls with dysmenorrhea were sent to mountainous regions for a short sojourn, thus changing their manner of living, it did them lots of good in that they rid themselves of this affection for months; but in some cases, when they returned to a life which was faulty so far as hygiene was concerned, the dysmenorrhea returned.

Dr. Sellman, in closing, said he had failed to recognize the connection between appendicitis and painful menstruation. He did not think it was a cause of dysmenorrhea.

The Menstrual Function: Its Influence Upon Chronic Inflammatory Conditions of the Appendix.—Dr. Francis Reder of St. Louis, Mo., said that after a painstaking consideration of the cases coming under his observation, only in the severest froms of adnexal disease could the inflammatory condition be said to communicate itself to the appendix and cause a primary acute disease. It was in the chronic form of appendicitis, be it a catarrhal or interstitial disease of the appendix, that pelvic hyperemia could arouse the dormancy of a smouldering appendix and provoke the clinical manifestations of an acute attack. In differentiating between abdominal and pelvic pain, the value of a vaginal examination must not be underestimated. In the cases seen by the author in which a diagnosis of appendicitis was made, there were important disclosures from such an examination. He did not believe that a menstrual hyperemia could provoke an acute attack in a healthy appendix. He did believe, however, that a menstrual hyperemia could incite an acute attack in an appendix that was diseased subacutely or chronically. The author reported several cases to support his contentions.

Lipthopedion, or Lithokelyphopedion.—Dr. Herman E. Hayd of Buffalo, N. Y., reported a case of lithopedion of thirty-two years' standing, which was successfully removed from a woman 68 years old. He also exhibited the specimen. He spoke of the rarity of the condition. He referred to the age of the specimen and its excellent preservation; the arms, legs, fingers, nails, hair, ears, and external genitals were all clearly shown. As to the clinical history, the specimen caused no symptoms for nearly thirty-two years. Reference was made to the possible changes that may take place in extrauterine pregnancy, such as suppuration, maceration, mummification, and calcification.

Dr. O. H. Elbrecht of St. Louis reported a case of tubal abortion, with complete detachment of the fetus from the placenta at six months, resulting in omental attachment and beginning lithopedion.

Ophthalmia Neonatorum: A Pathological Anachronism.—Dr. F. Park Lewis of Buffalo, by invitation, delivered an address on this subject, in which he advanced or suggested the following conclusions: 1. To secure the enactment of laws in each State or Federal Territory placing the supervisory control and licensure of midwives in the Boards of Health; requiring that they be examined and registered in each county, and that they be required to report immediately each case of ophthalmia occurring in their practice, under penalty, if found guilty, of forfeiture of their license and a fine. 2. Distribution by health boards of circulars of advice to midwives and mothers, giving instruction as to the dangers, method of infection, and prophylaxis of ophthalmia neonatorum. 3. The preparation and distribution by health boards of tubes containing the chosen prophylactic. For midwives 1 per cent. solution of nitrate of silver is almost universally recommended by obstetricians and ophthalmologists; for physicians the Credé solution, which should consist of 2 per cent. solution of chemically pure fused nitrate of silver. If used as directed by Credé (one drop from a glass rod) it is free from excessive irritation and absolutely safe. To insure purity of the drug and accuracy of dosage, the Credé solution should be given freely to physicians who make application therefor. This should be merely advisory. The Health Department should be free to use such prophylactic as it may deem best. 4. The accomplishment of these measures by the appointment of committees through the various State and county societies, whose cooperation would make concerted action possible. 5. To assure these ends, the cooperation of the American Association of Obstetricians and Gynecologists, the Academy of Ophthalmology and Oto-Laryngology, the American Ophthalmological Society, the American Public Health Association, and such other organizations as may appoint committees on ophthalmia neonatorum is urged. 6. If this plan of campaign be agreed upon, with such modifications as obstetricians, ophthalmologists and sanitarians may suggest, then a united and coordinated effort should be made to carry it into effect. Such an organized and concerted movement, steadily and effectively at work, would practically abolish ophthalmia neonatorum as a cause of blindness, thereby saving millions to the commonwealth and immeasurably increasing the happiness and efficiency of humanity throughout the world.

Back to an Old Idea.—This was the title of the President's address, which was delivered by Dr. Robert T. Morris of New York. He said the surgical patient was a factory. He had for his business the manufacture of phagocytes and opsonins for destroying bacteria. The new idea was to avoid disturbing this factory in such a way that it could not manufacture phagocytes and opsonins. The dominant idea in surgery to-day began with the studies of Pasteur and Semmelweis, formulated by Lister and continued by scientists of all countries, for the purpose of removing by the artifices of the surgeon the bacteria which caused disease. That idea had grown and had become dominant in surgery to-day. Exactly opposed to this was the new idea of letting the patient manage his bacteria, while the surgeons should let them alone. There were many ways for preventing this factory from manufacturing its full complement of phagocytes and opsonins, such as long-continued operations, extensive operations, free handling of viscera and tissues, long-continued anesthesia. Dr. Morris referred to the importance of rapid operating. Among the very earliest of ancient writers there was no reference to rapid operating. The relationship between the duration of an operation and the degree of shock was essentially a modern discovery. The old Romans made no reference to rapidity in operating. Celsus, after stating the requirements of a surgeon, said that he must be hard-hearted enough not to have compassion which would lead him to hurry. There was a distinction to be made between hurry in operating and rapidity in operating. Celsus had reference to the point of hurry to condemn it. Paré defined surgery as a quick motion of an intrepid hand, joined with experience. Heister, in the seventeenth century, quoted Celsus with approval and again made the statement that the surgeon should not hurry, but must be expeditious. Dr. Morris was fully agreed with those who argued against hurry in operating, but he believed surgeons should cultivate, as far as possible, rapidity of action, to the point that the average abdominal operation should require not more than fifteen minutes for its completion from beginning to end. Surgeons must drop many details in technique. The idea of details in technique was based upon the old dominant principle that the surgeon must remove bacteria. To-day it was held that the surgeon must cultivate speed in operating for the purpose of allowing his patient to manufacture his bacteria and opsonins, since the patient would manage his bacteria better than the surgeon could. Surgeons had been trying to do this conscientiously and scientifically, describing science as classified knowledge; but classified knowledge on this point had passed the vital point of con-

serving the resistance of the patient. This was the new idea. While it was not the dominant idea in surgery this year, he believed it would be the dominant idea in surgery in less than three years.

Premature Interruption of Pregnancy.—Dr. JOHN A. LYONS of Chicago said that, inasmuch as criminal abortion was constantly increasing, should not physicians assume the unpleasant duty of seeing that abortionists were prosecuted more vigorously, even if changes in the statutes were necessary? A campaign of education was essential for the benefit of the older as well as the younger married women, hoping to partially overcome the nerve-wasting, cruel tales of childbed. In the active treatment of incomplete abortion there was strong and intelligent opposition to the use of the sharp curette. Personally, he did not support either its pernicious or its promiscuous use in obstetrics, but followed more closely the practice of Von Winckel, who interfered when the temperature began to indicate a tendency to sepsis.

Surgical Treatment of Typhoid Perforations.—Dr. JOSEPH PRICE of Philadelphia said that the good practitioner and good nurse should not overlook a perforation of the bowel in a case of typhoid fever running a perfectly uniform course. Nearly all the perforations were within about the first twelve inches of the ileum. The characteristic symptoms of perforation were now well known. Typhoid and other perforations were always followed by peritonitis, local or general. The possibility of its remaining local or circumscribed by adhesions should not be considered if the diagnosis of perforation had been made. Perforation and hemorrhage were the two accidents in such cases that were commonly anticipated. In more than 75 per cent. of the cases recorded general septic peritonitis had been found, with escaping bowel contents, gas and feces, foul pus, and free exudate in considerable quantity. Generally the perforations were easily and quickly found near the ileocecal valve; rarely multiple or ragged, and, whether of large or small caliber, fine pure silk was the safest material. The surgeon could safely reduce the lumen of the bowel to one-half. If the margins of the ulcer were ragged, they should be trimmed. A resection was an unjustifiable and dangerous procedure. It was better to anchor the ragged ulcer and disorganize the bowel with catgut sutures on the opening between drains, forming an artificial anus or fecal fistula, which was a much safer procedure and was commonly followed by spontaneous closure. The repeated excuse for not operating on a typhoid perforation was low vitality of the patient, weakened condition, extreme emaciation. Successful operations had been done in the midst of low, alarming typhoid and abdominal conditions, general incontinence, muttering delirium, and subsultus. The triumphs following the repair of mutilations were now so numerous and gratifying the schooled surgeons should fear nothing.

In the discussion Drs. HERMAN E. HAYD, C. C. FREDERICK, JOHN A. LYONS, CHARLES L. BONIFIELD, WILLIAM H. HUMISTON, E. GUSTAV ZINKE, R. E. SKEEL, ALBERT VANDER VEER, JAMES F. W. ROSS, RALEIGH R. HUGGINS, JAMES E. SADLIER, RUFUS B. HALL, and HUGO O. PANTZER reported cases on which they had operated for typhoid perforation, some with successful, others with fatal results.

(To be continued.)

Inequality of the Pupils in Acute and Chronic Pleuro-Pulmonary Diseases.—R. Massalongo records observations as to the diagnostic value of inequality of the pupils in pulmonary diseases. His observations refer to pulmonary tuberculosis, acute pneumonia, bronchitis, and pleurisy. He finds that the symptom varies so much that no reliance can be placed on the indications based on its presence. Mydriasis may be present on only one side, or on both, or it may be absent. It has no clinical value, but is simply an accessory and secondary symptom. It has no diagnostic or prognostic value and its only interest lies in its physiopathology.—*Il Policlinico.*

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held May 21, 1907.

DR. GLENTWORTH R. BUTLER IN THE CHAIR.

Presentation of Patients Illustrating Early Recovery after Laparotomy.—Dr. RUSSELL S. FOWLER of Brooklyn presented the following patients: 1. A case of a female operated upon for appendicitis, who was allowed to move about freely in bed on the first and second day and to get up and walk about on the third day. 2. A patient operated upon for ovarian cyst, who walked about three days after the operation. 3. A patient who had had a left-sided intraligamentous cystoma, a right-sided pyosalpinx, and a fibroid, who walked about on the first day after the operation. 4. A case of acute appendicitis in which a five-inch median incision had been made, and which sat up on the first day and walked about on the third day after the operation. 5. A case of recurrent appendicitis that walked about on the first day. 6. A case of recurrent appendicitis that sat up in bed on the second day and walked about on the third day. 7. A case of acute appendicitis operated on with a three-inch incision, which walked about on the first day 8. A case of acute appendicitis, operated on with a three-inch incision, in which case the appendix ruptured on removal; the patient sat up in bed on the first and second day and walked about on the third day. 9. A case of appendicitis that walked about on the fourth day. 10. A case of large ventral hernia that got out of bed on the tenth day. 11. A case of acute appendicitis, in which the appendix was large and congested; the patient was up in bed on the first day and walked about on the second day.

Some Points in the Prevention and Treatment of Cystitis.—Dr. PAUL M. PILCHER of Brooklyn read this paper. He said that cystitis was always due to bacterial infection. Cases resembling closely true cystitis were those of congestion, edema, and hyperemia of portions of the bladder; they were not due to bacteria, but they frequently ended in cystitis. These congestions were caused by irritating lungs, exposure to cold, extensive burns of the body, traumatisms, highly acid urine, oxaluria, and retention of urine. Unless bacteria got into the bladder cystitis never resulted. The congestions and traumatisms were present frequently without any symptoms. In cases of extensive hysterectomies numerous ecchymoses often existed in the bladder, and in excessive cystocele pain, retention, and frequency of urination were due to hyperemia and edema of the trigonum and not to cystitis, for which they were often ineffectually treated. Cystitis did not develop until bacteria gained entrance, changing the urea to ammonium carbonate, which in turn irritated the bladder mucous membrane, preparing it for the fresh invasion of bacteria. The latter alone were not capable of causing cystitis. This was not likely to develop if the mucous membrane or other tissues of the bladder were uninjured. Bacilli could readily invade the bladder from the rectum. Seventy per cent. of the cases of cystitis were due to the colon bacillus. Instrumentation and retention of urine were the two most frequent predisposing causes of cystitis. Tubercular inflammation occupied a separate chapter. Cystitis developed after many cases of abdominal section in pelvic operations. Retention of urine, prolonged catheterization, with lack of aseptic precautions were the natural sequence in these cases. Clinically cystitis was classified according to location and distribution of the lesion, as localized cystitis involving generally the trigonum and base of the bladder, diffuse cystitis, and patchy cystitis. The etiological classification was: traumatic cystitis, cystitis due to extension of infection, obstructive cystitis, neoplastic cystitis due to the pressure of new growths and infection, and tubercular cystitis. In the localized and patchy cystitis there was frequently more healthy bladder mucosa than there was inflamed mucosa,

and Kelly pointed out that the use of strong solutions in these cases injured the healthy membrane. Cystitis developed most frequently at the trigonum and base of the bladder for the following reasons: They were the most dependent portion of the viscus, the mucous membrane was continuous with that of the urethra and the ureters, and it was most frequently injured by catheterism. Besides, the trigonum had a rich capillary supply. In cystitis due to obstruction the muscular bands of the bladder hypertrophied to form trabeculæ, with pockets of varying depths. Infection in this type of the disease was most intractable. Advancing inflammation caused destruction of tissue with formation and breaking down of abscesses and resulting unhealthy ulcers. In chronic cases the reason for the frequent failure of treatment was a lack of recognition of the underlying cause. The steps necessary to establish a diagnosis were: History of the illness, examination of the patient, examination of the urine, and examination of the mucous membrane of the bladder with the aid of the cystoscope. In the prevention of cystitis the cause had to be removed, strictures had to be dilated, hypertrophied prostate removed, acute distention of the bladder guarded against, and calculi and tumors of the bladder appropriately treated. Great care was necessary in giving urethral injections in the early stages of gonorrhea, which was a prolific source of infection. In catheterism the most careful asepsis was to be used in the preparation of the patient, instruments and operator's hands; care was to be taken not to injure the urethra, and the urine was to be allowed to escape slowly to prevent a violent grip of the catheter by the bladder wall. Following catheterism the speaker advised instillation of a few drops of a 1 to 1,000 solution of silver nitrate on the trigonum, and the administration of one of the milder urinary antiseptics. For the prevention of post-operative cystitis, particularly in gynecologic cases, the speaker's procedure was to avoid traumatism to the bladder during the operation, and if catheterization was afterward necessary, to perform this by means of a number 16 French catheter and to introduce afterward into the bladder 4 or 5 oz. of boric acid. A second injection of 8 oz. of the latter was advisable. A large syringe was preferable for the injection. Many cases could be rescued from catheterism by being induced to urinate voluntarily. The upright posture facilitated this, likewise a warm enema, hot moist cloths over the pubis, or the pouring of water from a container into another receptacle. In the treatment of cystitis the main point was the removal of the cause. In the acute cases bladder irrigation was contraindicated, except in the declining stage, if a gonorrheal cystitis. The treatment included rest in bed with the hips elevated, the administration of suppositories of opium, and belladonna to control the pain, heat to the perineum and above the pubis, and hot sitz baths, the free administration of diluent drinks, and, if the urine was highly acid, of mixtures containing potassium citrate and hyoscyanus; also the administration of hot rectal enemata. In his enthusiasm over urotropin, which was frequently useful, the practitioner often forgot the older drugs: infusions of buchu, linseed, and triticum repeus were often of value in acute cystitis, while in the subacute stage the oils of sandalwood, cubebs, and copaiba were useful for a few days at a time. The treatment of the chronic cases was divided into the nonoperative and the operative. For some cases rest in bed, drugs, and dieting regulations sufficed, but in most cases catheterism, irrigation of the bladder, and the use of some of the silver salts or of iodoform emulsion were necessary. In the gonorrheal cases oil of sandalwood or copaiba with salol was beneficial. For bladder irrigation warm sterile water was sufficient. For instillations solutions of silver nitrate (1-2 to 1 per cent.), argyrol (20 to 50 per cent.), and iodoform emulsion were useful. These were used after irrigation of the bladder, and then only a small quantity injected (as 2 oz. of a 1 2 per cent. solution of silver nitrate), which was to be retained by the patient for twenty minutes, and then passed voluntarily. Direct application was better, but this was only possible in the female in the knee-chest position, with the vesical mucosa in full view through a vesical speculum; stronger solutions were used, and where ulcers were present, these were cauterized by the silver stick or by carbolic acid or the actual cautery. Many cases resisted the ordinary methods of treatment. In prolapse of the uterus and cystocele the surgical correction of these deformities was necessary. In cases of contracted bladder with thickened walls and an old chronic cystitis, a vesicovaginal fistula frequently effected recovery. In the male suprapubic cystotomy or perineal section, with cleansing of the mucous membrane, the treatment of ulcerated surfaces or curettage of the entire bladder, with daily irrigation and, if necessary, topical treatment, was the procedure. In cases resisting all treatment, the existence of tubercular cystitis was to be suspected, and for this the safest method was the injection of 10 c.c. of urine into a guinea pig.

Direct Transfusion of Blood.—Dr. George W. Crile of Cleveland, O., read this paper. He said that in the early period surgery was heroic. The next stage in its evolution was the rise of the anatomic school. This was followed by the domination of pathology. Now the pathologic surgeon was beginning to add physiology. The question of transfusion was a broad one. It was practised for at least four centuries. It was more frequently performed before the development of chemistry, pathology, or bacteriology, and long before medical schools were established. Transfusion was performed almost exclusively with alien blood. This had given way to the transfusion of blood from one human being to another. This process had no adverse effect. The investigations of Dr. Follen of Yale revealed no metabolic changes resulting from this procedure. If after hemorrhage an individual received by transfusion an amount of blood equal to that lost, he was placed in the same condition that he was in before the hemorrhage. Death from shock was due to the failure of the supply of blood to the vasomotor centers, resulting in their functional breakdown. This created a vicious circle, the failure of the vasomotor center creating a still lower blood pressure, which in turn acted on the vasomotor center. *A priori* it was to be assumed that by transfusion the cause and effect of shock would both be combated. In fact, it was found that the influence of transfusion was the same on shock as on hemorrhage. The speaker's experiments had first been performed on dogs. He tried the effect of transfusion of blood in various toxic conditions. In strychnine poisoning transfusion following bleeding had no effect. These were similarly ineffectual in diphtheria toxemia. They had no effect in uremia following double nephrectomy. In gas poisoning, however, the transfusion of blood following bleeding produced recovery. Clinically the vascular systems of two individuals could be safely united. The speaker described his technique. In pernicious anemia the transfusion of blood had no effect on the course of the disease. In six cases of carcinoma transfusion was tried, but reports on these cases were not yet ready. It was thought that in cases of chronic suppuration it might have been possible to produce good results by means of a fresh supply of leucocytes through transfusion, but the effects were negative. Transfusion was tried in some cases of tuberculosis, but the experiments were too recent to report upon. It was hoped to be able to transfer immune and protective bodies from one individual to another. Six cases of chronic hemorrhage in gastric ulcers were relieved by transfusion. In severe jaundice due to carcinoma of the liver the hemorrhage was entirely controlled by means of transfusion and the patient's life was prolonged several months The therapeutic value of

transfusion was positive in acute hemorrhage and in shock, in which it was more valuable than any other method of treatment. Its value was negative in strychnine poisoning and diphtheria toxemia, and was still undetermined in chronic suppuration and malignant disease.

Stated Meeting, Held June 18, 1907.

Dr. Glentworth R. Butler in the Chair.

Presentation of a Case of Ichthyosis Simplex.—Dr. George F. Little of Brooklyn presented this case and detailed its history.

History of a Case of Infantile Scorbutus.—Dr. Eugene La F. Swan of Brooklyn read this paper.

Infantile Scorbutus.—Dr. John Lovett Morse of Boston read this paper. He said that almost every physician who had not the opportunity of observing many cases of infantile scurvy had in mind, as a picture of this disease, an infant, pale and ill-nourished, with spongy bleeding gums and showing the other classic symptoms of this disease. The milder cases were generally overlooked and were mistaken for difficult dentition. Of thirty cases seen by the speaker, besides the latter diagnosis, diagnoses of rickets, Pott's disease, hip disease, periostitis, gout, syphilis of the cord, acute nephritis, uric acid diathesis, and arsenical poisoning had been made. In most cases the physician was not acquainted with the disease infantile scurvy. The more definite symptoms were preceded by loss of appetite, malaise, pallor, failure to gain in weight. In only one-fourth of the cases were there bleeding from the gums and hematuria. In one-half of the cases was there tenderness in handling the little patient. The suddenness of onset and the severity of the cases varied. In one case, after a fall, loss of power in one leg suddenly developed. There were three groups of cases. In one group the cases were characterized by tenderness on handling, usually in the legs, and gradually increasing until the child ceased to use its legs. The thigh was flexed on the abdomen and the leg on the thigh. This class of cases was mistaken for rheumatism and paralysis. In some cases swelling of the gums appeared before the appearance of the teeth, and in other cases after their eruption. In some cases hematuria persisted for weeks or months, and the diagnosis of acute nephritis, tumor of the bladder, uric acid diathesis, etc., was made. If not treated these cases went on to bad and worse. There appeared swellings in the extremities, due to subperiosteal hemorrhages in the diatheses. These occurred most frequently in the lower portion of the femur, next in frequency in the upper part of the tibia, and then in the lower part of the humerus. The bone was not affected. These extremely severe cases were mistaken for osteomyelitis and acute superficial edema. Sometimes the hemorrhages occurred over the bones of the skull. There was no such expression of abject terror in any other condition in infants. Hemorrhages also occurred in the skin, roof of the mouth, eyelids, and intestinal wall, giving symptoms of tumor. Hemorrhage also occurred into the bone marrow. In spite of the hemorrhagic diathesis, external bleeding was unusual. Hematuria occurred in one-third of the cases. It was usually stated that scurvy was not accompanied by fever. There were many exceptions to this rule. There were cases having a temperature of 103° to 105° without complications. This caused confusion in diagnosis. Early diagnosis was possible in cases presenting anorexia, malaise, disturbed digestion, followed by loss of color, tenderness in legs and arms. Purplish cutaneous spots and hematuria sometimes preceded these. The legs were three times as frequently affected as the arms. The order of the appearance of symptoms varied. The onset was either sudden or insidious, with mild symptoms stretching over weeks or months before the condition was recognized. Most of the cases occurred during the second six months of life. The patient's surroundings had no direct influence on the disease. There was no relation between this disease and rickets. It sometimes occurred in breast-fed infants, but was most frequently found in infants fed on artificial foods. Next in frequency it was found in infants fed on overheated milk. It occurred in children fed on a milk mixture that was too weak. Absence of freshness in the milk was another cause. As to the cause of the disease it was variously assigned by different authors. Stokes attributed it to the destruction of the ferments in the milk, and Cohns to disturbance in absorption of calcium. Certain authors saw no connection between this disease and the sterility of the food, and saw in it a manifestation of autointoxication occurring in chronic dyspepsia. This argument was not convincing. The disease affected tissues that were young and in process of active growth. The local changes and the hemorrhagic diathesis were most marked. The bones were vulnerable points of attack. Hemorrhages occurred beneath the periosteum of the diaphysis, and into the marrow, the changes in the latter causing atrophy of the bone and ease of fracture. In the differential diagnosis the most important point was that the case improved rapidly on the treatment for scurvy. Rheumatism practically never occurred at this age. If it did occur, then the swellings were over the joints and not over the diaphises, and rheumatism was also accompanied by fever, while scurvy was not, nor was rheumatism accompanied by bleeding gums or hematuria. In periostitis and osteomyelitis there were tenderness and swelling in one extremity, and usually over one bone. There were all the signs of acute inflammation, always accompanied by high fever (which, however, did not rule out scurvy); leucocytosis was always present, but there were no bleeding gums. In hip disease there was limitation of motion in the hip, which was also swollen. Acute infectious arthritis of the hip gave the same symptoms as those of osteomyelitis and periostitis. In almost every case of scurvy a history of acute traumatism was usually elicited, so that some difficulty existed in ruling out traumatism as the cause of the symptoms. In paralysis there was a real loss of power in the extremity, which loss was not due to pain. In paralysis swelling did not occur. In infantile paralysis the onset was sudden; in scurvy it was slow. It was hard to understand how scurvy could be confounded with difficult dentition when the swelling developed about teeth that had already erupted. The spongy and bleeding gums were practically never seen in difficult dentition. Sometimes in scurvy hematuria was the earliest and only symptom. In infants hematuria was rare, except as a manifestation of scurvy. The therapeutic test of scurvy was the administration of fresh orange juice. The latter was taken more readily by the babies than lemon juice. It was best to give a definite amount, about two tablespoonfuls, daily; a larger amount gave no better results. It was given one hour before each feeding. Fresh beef juice was less rapid in its effect than fresh fruit juice. It was frequently necessary to change the food. Some modification of cow's milk was necessary, but it was never to be sterilized. Many patients recovered with a mere change of the food, but recovery was slow. Improvement sometimes took place on a less suitable food. Drugs were not necessary. It was sometimes necessary to immobilize the limb. The pain and tenderness were the first to yield; the gums, later. The disappearance of swelling about the bones was slow. Improvement was noticed within a week; some cases were entirely well in five days. Recovery was almost complete in three weeks.

Typhoid Fever in Infancy and Childhood.—Dr. Louis C. Ager of Brooklyn read this paper. He referred to the fact that for a long time the prevalence of typhoid in early life was overlooked. This was due to the marked differ-

ence from the adult type. Every case of continued or remittent fever in children was to be regarded with suspicion, and the Widal test repeatedly tried, if necessary, before typhoid was excluded. The general practice of the Widal test would probably show that infants under two years were subject to typhoid more often than was at present suspected. As late as 1900 Dr. Northrup had insisted that infants under two years were not susceptible to typhoid, he and others basing this conclusion upon a review of several thousand autopsy records which failed to show a single case of typhoid in a child under two years. Since the compilation of these statistics two important advances had been made. First, the Widal test, and second, the recognition that in young infants autopsy findings after typhoid were too diverse to be of diagnostic value. In a recent analysis of 145 cases of typhoid fever in children, over seven per cent. were under two years. After this age typhoid fever became much more common. Typhoid fever was less frequent in childhood than in early adult life, but the difference had been greatly exaggerated in the past. As children were as frequently exposed to typhoid infection as adults, they were in some way able to resist that infection, either by means of a specific immunity, or by means of conditions in the digestive tract unfavorable to the development of the bacillus. These conditions were possibly either the ease with which the intestine emptied itself, or else the fact that the prevailing bacteria of the infantile small intestine were of the lactic acid group, the colon bacillus rarely occurring above the colon until a mixed diet took the place of milk. As regarded the mode of infection, milk was most frequently at fault. The pathological lesions in children were much less marked than in adults, which probably accounted for the shorter period of pyrexia. Extensive ulceration of the aguimated glands was very unusual, and cases were on record in which no intestinal lesions were found. For accurate diagnosis the Widal test was essential; it was to be applied at frequent intervals throughout the disease or until a diagnosis was established. The diazo reaction was obtained earlier, but it was also obtained in a variety of intestinal toxemias in children. There was no one clinical symptom that was always present, and there was no symptom of typhoid that might not be found in other diseases. Typhoid was usually prevalent when children were affected. The younger the child the more irregular were the symptoms. Lobar pneumonia with delayed physical signs closely simulated typhoid. Age was an important factor in the symptomatology. Under three years the disease often had the appearance of a subacute gastroenteritis with mild cerebral symptoms, the temperature being very irregular, often remittent, the stools green and watery, tympanites slight or absent, and delirium unusual. Emaciation was rapid and prostration was extreme. The more frequent type of typhoid of children was like the mild typhoid of adult life. In most cases the spleen was moderately enlarged by the second week, but owing to its mobility and softness very careful palpation was needed to recognize it. Diarrhea was not as frequent as in the adult and was rarely severe. Moderate constipation was often present. The eruption varied greatly. The temperature at the onset was apt to be higher than in the adult, and during the first week remained high. The diurnal variations in the temperature curve were a frequent cause of a mistaken diagnosis of malaria. The temperature pulse ratio, if properly interpreted, was of great diagnostic and prognostic importance, sounding the alarm of the various complications, particularly perforation, hemorrhage, or pneumonia, before other signs appeared. The most important characteristic of the course of the fever in children was its usual short duration. The ordinary typhoid delirium was unusual. If the fever was prolonged beyond two weeks the myocardium soon gave evidence of degenerative changes. Bronchitis was so common in typhoid as to constitute a symptom rather than a complication. Pneumonia not infrequently accompanied or followed typhoid. The nervous system was frequently the seat of complications in typhoid. These were meningeal irritation, mild neuritis, and chorea; otitis, suppuration of joints, and tubercular infection also occurred. Intestinal hemorrhage occurred in three per cent. of the cases, and the mortality was nearly fifty per cent. Intestinal perforation was rarer. Myocardial degeneration was one of the most dangerous results of typhoid fever. It was more easily overlooked and more lasting than the other complications. In the speaker's experience the death rate was under four per cent. In the treatment the question of diet was the most important problem. The patient was to be fed exactly as in any other form of acute ulcerative ileocolitis. One of the most tenacious and pernicious of medical superstitions was the idea that typhoid spelled milk diet. It was logical to stop the milk in typhoid just as in any of the hot weather disturbances of the digestive tract in children. Instead, for the first few days was to be given nothing but plenty of cold drinks, plain or carbonated, and cold tea, which was slightly stimulating. Later dextrinized gruels, hot or cold broths, beef juice, raw egg whey, and ice cream made with whey or malted milk, and the various proprietary foods furnished ample nourishment. In mild cases, with the drop in the temperature at the end of a week or ten days, it was wise to begin with peptonized milk, and then add milk toast, soft eggs, and bread and butter as they were demanded. Inanition fever was cured by feeding, not by starvation. For headache, restlessness, and fever, hydrotherapy was usually successful. Cold immersion baths were not well borne, but frequent lukewarm sponging was distinctly soothing and brought the blood to the surface where it was cooled by radiation. The ice cap relieved headache, produced sleep, and had a definite effect upon the temperature. Coal tar products were to be avoided. For the enterocolitis the most useful drug was castor oil, which was soothing and astringent, and carried off putrefactive products. The use of the antifermentatives was based upon reason and was justified by clinical experience. The speaker had a growing prejudice against alcohol as a stimulant, justified by recent English studies as to its effect on the liver of the child. If it was indicated, pure alcohol diluted was better than the unknown proprietaries like brandy and whiskey. Aromatic spirits of ammonia in doses of 20 to 10 minims was better. In the choice between strychnine and digitalis it was necessary to remember that the former influenced the heart through the spinal ganglia, while the latter acted directly upon the myocardium and the blood-vessels. The latter action was an advantage in the face of the tendency toward vasodilatation in typhoid. In sudden alarming collapse the tincture of capsicum in oil or water administered per rectum acted more powerfully and quickly than any other drug tried. For a rapid and irritable heart due to the fact that the patient was tired from lack of sleep, codeine in small doses was the best remedy. In case of hemorrhage collapse was not to be allowed to go beyond control, and blood pressure had to be kept at the lowest possible limit of safety. In children codeine phosphate controlled the situation about as well as morphine. Adrenalin was still recommended, but it had no systemic action when administered by mouth. In case of perforation the one justifiable course was operation.

The speaker emphasized three points: 1. The fact that typhoid in children was usually a mild disease was no excuse for not recognizing and saving the severe cases. 2. What the child absorbed from the intestinal tract, not what the nurse forced into it, was the sole determining factor in diet. 3. A belief in therapeutic simplicity was no excuse for drug ignorance and inactivity in typhoid fever or in any other disease of childhood.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 12, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	332	143
Diphtheria	272	23
Measles	114	4
Scarlet Fever	164	5
Smallpox	..	..
Varicella	22	..
Typhoid Fever	163	32
Whooping Cough	14	3
Cerebrospinal Meningitis	11	8
Malarial Fever	..	..
Totals	1092	218

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service during the week ended October 11, 1907:

SMALLPOX—UNITED STATES.

		Cases.	Deaths
California, San Francisco	Sept. 15–21	1	..
Indiana, Anderson	Sept. 1–30	2	..
Elkhart	Sept. 22–28	2	
Iowa, Davenport	Sept. 1–30	2	
Michigan, Detroit	Sept. 22–28	6	
Saginaw	Sept. 22–28	1	..
Missouri, St. Joseph	Sept. 20–26	1	
Montana, Six Counties	Aug. 1–31	7	..
Ohio, Cincinnati	Sept. 29–Oct. 4	2	..
Oregon, Twelve Counties	April 1–July 31	42	..
Nebraska, Omaha	Feb. 1–Sept. 30	44	..
Texas, Temple	Sept. 22–28	2	..
Washington, La Crosse	Sept. 22–28	1	..
Milwaukee	Sept. 22–28	4	..
Spokane	Sept. 22–28	1	..

SMALLPOX—FOREIGN.

Africa, Lorenz Marquez	July 1–31	..	5
Sierra Leone	Aug. 1–31	2	1
Austria, Galicia	Aug. 1–31	4	..
Monrovia	Aug. 18–31	1	..
Vienna	Sept. 1–7	35	6
Brazil, Para	Sept. 14–21	5	6
Canada, Halifax	Sept. 22–28	1	
China, Hongkong	Aug. 18–24	1	1
Shanghai	Aug. 10–25	1	10
	Cases foreign,	Deaths native	
Columbia, Cartagena	Sept. 11–17	..	Present
Ecuador, Guayquil	Sept. 1–7	..	2
Egypt, Cairo	Aug. 11–19	..	1
India, Bombay	Aug. 27 Sept. 3	..	1
Madras	Aug. 24–30	..	3
France, Paris	Sept. 8–14	5	1
Toulon	Aug. 1–31	2	..
Italy, General	Sept. 6–19	38	
Java, Batavia	Aug. 18–24	3	
Madeira, Funchal	Sept. 9–15	3	
Malta, Valletta	Sept. 8–14	2	
Mexico, Aguas Calientes	Sept. 15–28	..	2
Persia, Mash-Had	July 1–31	..	Present
Rasht	July 1–31	..	"
Shiraz	July 1–31	..	"
Tibre z	July 1–31	..	"
Peru, Lima	Sept. 7	..	1
Portugal, Lisbon	Sept. 7–14	3	..
Russia, Libau	Sept. 1–7	1	..
Odessa	Sept. 1–7	1	
Riga	Sept. 8–14	1	
Warsaw	Aug. 4–17	..	7
Spain, Barcelona	Sept. 11–20	..	3
Denia	Aug. 1–31	2	
Malaga	Aug. 1–31	..	7
Valencia	Sept. 8–15	22	1
Turkey in Europe, Constantinople	Sept. 9–15	..	3
Turkey in Asia, Bagdad	Aug. 11–21	..	Present

CHOLERA.

China, Shanghai	Aug. 19–25	3	18
	Cases among foreigners.	Deaths among natives.	
India, Bombay	Aug. 28–Sept. 3	..	53
Calcutta	Aug. 18–24	..	25
Madras	Aug. 24–30	..	20
Moulmine	July 7–27	42	
Rangoon	Aug. 18–24	..	5
Japan, Fukuoka Ken	To Sept. 9	84	
Mon	To Sept. 9	408	114
Hiroshima Ken	Sept. 1–9	2	
Hyrogo Ken, Kobe	To Sept. 9	5	2
Oita Ken	Sept. 1–9	4	
Okugori Ken	Sept. 1–9	27	
Yamaguchi Ken	Sept. 1–9	92	
Shimonoseki	To Sept. 4	30	
Korea, Seoul	Sept. 26	..	Present
Straits Settlements, Singapore	Aug. 4–17	..	92

YELLOW FEVER.

Brazil, Manaos	Sept. 1–14	..	3
Para	Sept. 15–21	6	3
Costa Rica, San Jose	Sept. 15–21	1	Imported
Cuba, Cienfuegos	Oct. 3–4	2	..
Total from	Aug. 3–Oct. 4	64	16
Habana	Oct. 7	1	..
Palos	Oct. 3	2	1
Ecuador, Guayaquil	Sept. 5–14	..	1

EXPERIENCES WITH THE BEAD TEST FOR ASCERTAINING THE FUNCTIONS OF THE DIGESTIVE APPARATUS.

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

In two previous papers* I have dealt with the physiological conditions of several nutritive substances in the stomach and bowel, as shown by the bead test; later I also used the test for examining the functions of the digestive apparatus.

I would now like to detail my latest experiences with the bead test and thereon discuss a few new points.

From October, 1906, to May, 1907, I used the bead test frequently and have grouped the results in a table.

On examining this table we can divide the items into two large groups: A. Diseases of the digestive tract (1-68). B. Diseases of other organs (69-109).

Group A. We first have twelve cases of achylia gastrica with 14 tests. Motility was normal in six, accelerated in five, and considerably retarded in one. In seven the digestive functions were fairly good, in five they were bad, *i.e.* most of the substances were returned unchanged.

In 15 cases of hyperchlorhydria decreased motility was shown by 4, increased by 2, the rest showed normal motility. The digestive functions were good in 4, whereas they were disturbed in eleven cases; 3 suffered from a lack of fat digestion, 3 from a lack of starch digestion alone, whereas in 4 a combination of impaired fat and starch digestion occurred.

Case 17, nervous gastralgia and colitis, and case 18, atony of the stomach with cardiac arrhythmia, show normal digestive functions. In 3 cases of chronic gastritis (33, 34, 35) motility was accelerated twice, normal once, whereas the digestive power was good with the exception of starch, which was slightly disturbed.

In 6 cases of chronic enteritis (36, 44, 46, 47, 48, 49) there was normal motility in 3, accelerated in one, and retarded in two. The digestive function was good in two, impaired in four; in one case there was a diminution in the power of fat digestion, in one of fat and starch digestion, in two of starch digestion only.

In five cases of chronic constipation (37, 38, 43, 50, 51) there was normal motility in one and retarded motility in four. In four the digestive function was good, and in only one (43) fat digestion was impaired.

In two cases of atony of the stomach with migraine (40, 41) both motility and digestive function were good. In one case of atony of the stomach and periodical vomiting (42) motility was normal and the power of digestion for fat and starch diminished.

Two cases of grave chronic gastroenteritis (52, 57) showed at first accelerated motility and poor digestive power; later, after treatment, a more normal motility and considerably better digestion.

In one case of enteralgia (54) there was normal motility and disturbed digestion for fat and starch.

Three cases of colitis (55, 56, 60) all showed a retarded motility but good digestion.

Case 61, obesity and intestinal dyspepsia, showed retarded motility and poor proteid digestion.

Two cases of ulcer of the stomach (62, 63) showed in one normal and in one retarded motility; in one there was found a disturbed starch digestion, in the other disturbed fat digestion.

Three cases of splenomegaly (64, 65, 66) showed in one normal, in one accelerated, and in one retarded motility. In two fat digestion was impaired. In one starch digestion.

Case 67, nervous gastralgia, showed retarded motility, but good digestion.

Case 68, flatulency, showed increased motility and disturbed starch digestion.

Group B. A case of sciatica (69) showed good motility and digestion; a case of myelitis (70), good motility and somewhat impaired starch digestion.

A case of pneumonia (71) after the crisis showed retarded motility and good digestion.

A case of arteriosclerosis (72) showed retarded motility and good digestion.

Three cases of grave malaria (73, 74, 75) showed good motility in two, retarded in one, whereas the digestive function was disturbed in all as regards fat and in two for starch.

Two cases of diabetes mellitus without coma (76, 77) showed normal motility in one, retarded in one, with good digestion. One case of diabetes mellitus with slight coma and some fever (78) showed considerably retarded motility (11 days) and diminished fat digestion.

One case of splanchnoptosis (79) showed good motility and digestion.

In six cases of typhoid fever (80, 81, 83, 84, 85, 86) there was increased motility in one, retarded in one, and normal in four. The digestive function was absolutely poor in two cases, whereas in four there was a disturbance of either starch or fat digestion or both. Fish bone was found in five, whereas thymus was present in all. Case K (81, 82) was particularly interesting, because all the substances were here recovered during the fever stage, whereas a week after the occurrence of normal temperature the digestion was considerably better.

A case of gallstones without jaundice (87) showed normal motility and digestive functions.

Three cases of jaundice (88, 89, 90) showed in one normal, in two retarded motility. Fat digestion was disturbed in all, starch digestion in one.

*Max Einhorn: A New Method of Testing the Functions of the Digestive Apparatus. Medical Record, February 10, 1906. And Further Remarks on the Digestive Bead Test for Ascertaining the Functions of the Digestive Apparatus. *Journal of the American Medical Association.* February 2, 1907.

TABLE OF THE NEW CASES EXAMINED WITH THE BREAD TEST. (October, 1906, to May, 1907.)

No.	Name	Disease	Beaustring when found	Result	Remarks
1	Mrs. And.....	Achylia gastrica.....	After 36 hours	Everything disappeared except ½ thymus. Nuclei not found.	
2	B.....	" "	" 89 "	Catgut, fishbone, meat disappeared; fat present; the other heads were lost.	
3	Mrs. Ac..... XII, 29, '06.	" "	" 22 "	Everything disappeared except thymus and ½ potato.	Ultramarine disappeared
4	Mrs. Ac..... III, 25, '07.	" "	" 24 "	Everything disappeared except thymus, meat, potato. Nuclei present. Fishbone was not used.	
5	Mrs. F.....	" "	" 23 "	Everything disappeared except thymus and ½ potato. Nuclei disappeared.	Ultramarine a trace.
6	S.....	"	" 24 "	Everything disappeared except thymus and trace potato. Nuclei gone.	Ultramarine a trace.
7	Dr. J. T. R.....	" "	" 27 "	Everything disappeared except thymus and ½ potato.	
8	Dr. St.....	" "	" 23 "	Everything disappeared except thymus, fat, fishbone and ½ potato.	Ultramarine a trace.
9	Mrs. W.....	" "	" 20 "	Everything disappeared except thymus, meat, potato. Nuclei gone.	
10	Mrs. McE.....	" "	" 26 "	Thymus, potato, ½ fat, ½ meat present. Nuclei present. Fishbone and catgut gone.	
11	E. S. N..... X, 14, '06.	" "	" 21 "	Thymus, meat, fishbone, catgut, ½ potato present. Nuclei and fat disappeared.	Ultramarine unchanged. Thread with potass. permang.; discolored.
12	E. S. N..... XI, 20, '06.	" "	" 19 "	Thymus, meat, catgut, potato present. Fat, fishbone disappeared.	Ultra marine present.
13	Mrs. H.....	" "	" 24 "	Everything disappeared except ½ thymus. Nuclei gone.	
14	Mrs. W. R. B....	" "	" 34 "	Everything disappeared except ½ potato.	
15	Mrs. Sch.....	Atonia ventriculi Hyperchlorhydria.	" 38 "	Everything disappeared.....	Zinc sulphide ½ present.
16	K.....	Hyperchlorhydria.....	" 36 "	" "	
17	C. S. P.....	Gastralgia nervos. Colitis	" 43 "	" "	Ultramarine disappeared.
18	McE.....	Atonia ventriculi. Arrhythmia cordis.	" 26 "	" "	" "
19	Br.....	Atonia ventriculi. Hyperchlorhydria.	" 44 "	Everything disappeared, except ½ fat.	
20	Mrs. A.....	Atonia ventriculi. Hyperchlorhydria.	" 34 "	" " " fat.....	Ultramarine disappeared.
21	St.....	Hyperchlorhydria.....	" 102 "	" " " " and ½ thymus. Nuclei gone.	
22	A.....	Atonia ventriculi. Hyperchlorhydria.	" 34 "	Everything disappeared except ½ thymus. Nuclei gone.	Ultramarine present.
23	M.....	Hyperchlorhydria.....	" 52 "	Everything disappeared except a trace of thymus.	Ultramarine disappeared.
24	C.....	Hypersecretion continua chronica.	" 22 "	" " " ½ thymus, ½ potato and nuclei.	Ultramarine disappeared.
25	Dr. G.....	Atonia ventriculi Hyperchlorhydria.	" 18 "	Everything disappeared except ½ thymus and trace potato. Nuclei gone.	Ultramarine disappeared. Potass. permangan. thr'd discolored.
26	Mrs. D.....	Hyperchlorhydria.....	" 38 "	Everything disappeared, except thymus. Nuclei partially present.	Ultramarine disappeared.
27	L.....	Hyperchlorhydria. Dilatatio ventriculi.	" 46 "	Everything disappeared except fat and fishbone..	
28	C.....	Hyperchlorhydria.....	" 33 "	" " " thymus and fishbone. Nuclei gone.	Ultramarine present.
29	G.....	"	" 24 "	Everything disappeared except fat, ½ thymus, ½ potato. Nuclei gone.	
30	M.....	" Insufficiency of mitral valve.	" 28 "	Thymus fat, ½ potato present. Everything else, including nuclei, disappeared.	
31	Dr. R. III, 25, '07.	Hyperchlorhydria. Dilatatio ventriculi. Colitis.	" 18 "	Thymus, meat, fishbone, potato, present. Fat, catgut, nuclei disappeared.	
32	Dr. R., IV, 15, '07.	Hyperchlorhydria Dilatatio ventriculi. Colitis.	" 27 "	Everything disappeared.	
33	St.....	Gastritis chronica	" 12 "	" " except ½ potato.	
34	Dr. B.....	" "	" 36 "	" " " trace thymus and trace potato. Nuclei gone.	
35	Mrs. J.....	" " Enteritis chronica.	" 17 "	Everything disappeared, except fat and ½ potato.	
36	T.....	Enteritis chronica. Atonia ventriculi.	" 30 "	" " " trace thymus. Nuclei gone.	
37	I.....	Atonia ventric. Constip. spastica.	" 47 "	Everything disappeared except ½ thymus. Nuclei gone.	
38	R.. IX, 20, '06.	Dilatatio ventriculi. Constip. spastica.	" 50 "	Everything disappeared except trace fat.	
39	R.. IX, 20, '06.	Dilatatio ventriculi. Constip. spastica.	" 50 "	" " " trace thymus. Nuclei gone.	Ultramarine disappeared.
40	Rev. K.....	Atonia ventriculi. Migraine	" 36 "	Everything disappeared.	
41	Mrs. McG.....	Anemia, migraine. Atonia ventriculi.	.....	Everything disappeared, fat, bead was not recovered.	
42	W.....	Atonia ventric. Periodic vomiting. Constip. spast	After 26 hours	Everything disappeared except fat and potato.	
43	Miss K.....	Constipatio spastica. Coli.	" 46 "	Everything disappeared except thymus and fat.	Thread grayish blue.
44	Dr. F., X, 12, '06	Enteritis chronica.....	" 54 "	" " " " fat.....	Ultramarine disappeared.
45	Dr. F., X, 25, '06.	" "	" 65 "	" " " " ½ thymus. Nuclei gone.	Ultramarine disappeared.
46	Miss M.....	Enteroptosis. Dilatatio ventric. Enteritis chr.	" 20 "	Fishbone, fat, and ½ potato present, everything else disappeared.	
47	McN.....	Enteritis chron. Dilatatio ventriculi.	" 28 "	Trace thymus, ½ potato present. Everything else, including nuclei, disappeared.	Ultramarine disappeared.
48	P.....	Enteritis chron.....	" 22 "	Thymus and ½ potato present. Everything else, including nuclei disappeared.	Ultramarine present.
49	Dr. B.....	Enteritis chronica. Hyperchlorhydria.	" 38 "	Everything disappeared.....	Ultramarine disappeared.
50	R.....	Constipatio.....	" 34 "	Thymus present. Nuclei and everything else disappeared.	Ult'amarine pres't. Potassis. permang. Thread disc'l'r'd.
51	Mrs. St.....	Constipatio spastica.....	" 56 "	Everything disappeared.....	Ultramarine disappeared.
52	Mrs. K., I, 29, '07	Gastritis chronica. Enteritis chr. Dilatatio ventric.	" 15 "	Thymus, potato, meat, catgut, fishbone, present Fat and nuclei disappeared.	Ultramarine disappeared.
53	Mrs. K., II, 1, '07	Gartritis chronica. Enteritis chr. Dilatatio ventric.	" 30 "	Everything disappeared except thymus and fat.	
54	Miss. D.....	Enteralgia.....	" 20 "	Potato, ½ thymus, ½ fat present. Everything else, including nuclei, disappeared.	Ultramarine disappeared.
55	Mrs. M.....	Colalgia, enteritis, membranacea. Constipatio.	" 00 "	Everything disappeared.	
56	O.....	Colitis.....	" 43 "	" "	
57	O'D., I, 24, 07...	Gastritis chron. Enteritis chronica.	" 14 "	Thymus, potato, meat, present. Nuclei and everything else disappeared.	Ultramarine present.
58	O'D., II, 2, '07...	Gastritis chron. Enteritis chronica	" 26 "	Thymus, and ½ potato present, Nuclei and everything else disappeared.	
59	OD., III, 12, '07	Gastritis chron. Enteritis chron.	" 64 "	Everything disappeared.	
60	Mrs. B.	Colitis, neurasthenia.....	" 55 "	½ thymus present; nuclei and everything else disappeared.	
61	Mrs. S.	Adipositas. Dyspepsia intestinalis.	" 46 "	Thymus, meat, fishbone present. Potato, catgut, nuclei disappeared. Fat bead not found.	

TABLE OF THE NEW CASES EXAMINED WITH THE BREAD TEST. (October, 1906, to May, 1907.)—*Continued.*

No.	Name	Disease	Beaustring when found	Result	Remarks
62	A.	Ulcer of stomach	After 22 hours	Thymus, potato present. Nuclei and everything else disappeared.	
63	S	" " "	" 42 "	Fat and ½ thymus present. Nuclei and everything else disappeared.	
64	A.	Splenomegalia	" 71 "	Thymus and fat present. Nuclei and everything else disappeared.	
65	K.	"	" 18 "	Thymus and potato present. Nuclei and everything else disappeared.	
66	G.	"	" 34 "	Fat and fishbone entirely, thymus and nuclei partially present. Everything else disappeared.	Ultramarine present.
67	Mrs. N.	Gastralgia	" 38 "	Everything disappeared.	
68	Dr. E.	Flatulence	" 20 "	" " except potato.	
69	N.	Sciatica	" 23 "	" " Thymus and potato beads not found.	Ultramarine present.
70	F.	Myelitis	" 26 "	½ thymus, ½ potato nuclei partially present. Everything else disappeared.	
71	L	Pneumonia	" 92 "	Everything disappeared	1 day after crisis.
72	B.	Arteriosclerosis	" 45 "	" "	
73	P.	Malaria	" 18 "	Fat, ½ thymus, ½ potato present. Everything else disappeared.	
74	K.	Malaria	" 27 "	Fat, thymus, ½ potato present. Nuclei and everything else disappeared.	Free from fever.
75	W.	Malaria	" 41 "	Fishbone, fat, ½ thymus present; everything else disappeared.	
76	K.	Diabetes mellitus	" 65 "	½ thymus present. Nuclei and everything else disappeared.	
77	Mrs. W.	" "	" 24 "	Everything disappeared.	
78	L.	" "	" 204 "	½ thymus, ½ fat present. Nuclei and everything else disappeared.	
79	Mrs. A.	Enteroptosis. Nephroptosis on both sides Hepat's.	" 32 "	Trace of thymus and trace fat present. Nuclei and everything else disappeared.	
80	Ch.	Typhoid	" 18 "	Thymus, fishbone, potato present. Nuclei and everything else disappeared.	Temperature remitting.
81	Kr., IV, 5, '07.	Typhoid	" 41 "	Everything present.	Temperature remitting.
82	Kr., IV, 13, '07.	Typhoid	" 19 "	Fat, fishbone, ½ thymus, ½ potato present; everything else disappeared.	Temperature normal for ≦1 week.
83	K.	Typhoid	" 16 "	Thymus, fishbone, meat, ⅔ potato present. Nuclei and everything else disappeared.	Fever stage.
84	D.	Typhoid	" 102 "	Fishbone, fat, thymus present. Nuclei and everything else disappeared.	Fever stage.
85	P.	Typhoid	" 22 "	Fishbone and thymus present. Nuclei and everything else disappeared.	At the height of disease.
86	Ki.	Typhoid	" 21 "	Fat and ½ thymus present. Everything else disappeared.	
87	Mrs. L.	Cholelithiasis	" 34 "	Trace potato present. Everything else disappeared	Ultramarine present.
88	A.	Cholelithiasis, icterus	" 23 "	Potato, ½ thymus, ½ fat, a few nuclei present. Everything else disappeared.	
89	Mrs. Sch.	Icterus	" 40 "	Everything disappeared, except trace fat.	
90	B.	"	" 40 "	Fat, ½ thymus present. Nuclei and everything else disappeared.	
91	L., XII, 8, '06.	Icterus, hepatitis	" 18 "	Everything present; nuclei partially	Ultramarine present.
92	L., XII, 18, '06.	" "	" 28 "	Everything disappeared except fishbone, potato, thymus and ½ fat.	Ultramarine present.
93	L., I, 9, '07.	" "	" 16 "	Everything present, except catgut. Nuclei gone.	
94	M.	Cirrhosis of liver, ascites	" 59 "	" "	
95	Z., II., 27, '07.	Cirrhosis of liver, ascites and general miliary tuberc'l's.	" 19 "	" present.	
96	Z., III, 11, '07.	Cirrhosis of liver, ascites and general miliary tuberc'l's.	" 22 "	" " nuclei partially.	
97	D.	Cirrhosis of liver. Pleurisy	" 37 "	Everything disappeared except fat and ½ thymus.	
98	M.	" " " Icterus, ascites.	" 18 "	Fishbone, potato, thymus, ½ fat present. Nuclei, catgut, meat, disappeared.	
99	B.	Cirrhosis of liver	" 90 "	Everything disappeared, except trace fat and trace thymus.	
100	D., XII, 10, '06.	Cirrhosis of liver.. Ulcer of stomach.	" 30 "	Everything disappeared, except trace potato	Ultramarine disappeared.
101	D., XII, 18, '06.	Cirrhosis of liver. Ulcer of stomach	" 33 "	" " " ½ fat and trace potato.	Ultramarine disappeared.
102	Mrs. St.	Cancer of stomach and liver, icterus.	" 17 "	Thymus, potato present. Everything else, including nuclei, disappeared.	Ultramarine present.
103	C., IV, 10, '07.	Tumor of liver, icterus	" 18 "	Everything present, except catgut and nuclei	HCl + Ac = 56.
104	C., IV, 20, '07.	" " " "	" 38 "	Thymus, fat, fishbone, nuclei, present. Everything else disappeared.	
105	C., IV, 30, '07.	" " " "	" 46 "	Fat, fishbone, ½ thymus, present. Nuclei and everything else disappeared.	
106	W.	Aneurysm of aorta	" 92 "	Everything disappeared, except fat and fishbone.	
107	R.	Pleurisy, eosinophilia	" 62 "	Fishbone, thymus present. Nuclei and everything else disappeared.	
108	Gr.	Trichinosis	" 16 "	Everything disappeared, except fat and fishbone.	
109	G.	Delirium tremens	" 19 "	" present, except fat. Nuclei gone.	

A case of syphilis of the liver with chronic jaundice (91, 92, 93) showed normal, occasionally increased, motility, and poor digestive function, as nearly everything returned unchanged.

Six cases of cirrhosis of the liver (94, 95, 97, 98, 99, 100) showed delayed motility only twice. The digestive function was good in two, poor in one (complicated with miliary tuberculosis), as all substances returned unchanged, and in three digestion was insufficient for fat and carbohydrates or for fat alone.

Case 102, cancer of the liver and stomach with jaundice, showed increased motility and disturbed starch digestion.

A case of malignant tumor of the liver with chronic icterus (103, 104, 105) showed accelerated motility once, retarded twice, and usually bad digestive functions. Once the thymus nuclei were well preserved.

Case 106, aneurysm of the aorta, showed considerably retarded motility and poor fat digestion.

Case 107, pleurisy and eosinophilia, showed retarded motility but good digestive function. A case of trichinosis (108) showed accelerated motility and poor fat digestion.

A case of delirium tremens (109) showed somewhat increased motility and an absolutely poor digestive function, as everything was found unchanged except fat; the nuclei had also disappeared.

From the above facts we can gather that the bead test gives a true picture of the digestion; thus at the height of the disease we frequently find a worse state of digestion than during convalescence. The results are not always the same in the same disease, as they are influenced by the individual peculiarities of the patient.

Marked disturbance of the digestion (for nearly all nutritive substances) is found in barely half of

the cases of achylia, in delirium tremens, in some grave cases of gastroenteritis, and sometimes in typhoid fever.

A diminution in starch digestion is a very frequent occurrence and is often found; disturbances of proteid digestion alone, however, are very rare.

FIG. 1.—Thymus gland, squeezed out; nuclei distinctly visible all over.

In purely nervous affections, pure colitis, and constipation the digestive function is generally very good.

In connection with the bead test I would like to mention a few points concerning the testing of the digestive function. In making the test it is of importance to have specific substances for the various sections of this long canal. Schmidt has suggested two such substances, connective tissue for the stomach and nuclei for the pancreas.

Concerning the connective tissue, I have shown in my former papers that it can also be digested in the bowel, as was evidenced by various catgut experiments. Schmidt, however, maintains that catgut is different from raw connective tissue.

FIG. 2.—Thymus gland (after passing through the digestive tract) squeezed out; no nuclei present; only detritus.

To decide this point the following experiment was made: One piece of raw connective tissue was placed in 5 c.c. of filtrate of stomach contents, and another equally large piece of raw connective tissue in 5 c.c. of diluted trypsin solution one to three. They were kept at blood temperature. After one hour the connective tissue in the gastric filtrate had disappeared. After 24 hours about one-tenth of the connective tissue was still present in the trypsin solution; after 48 hours scarcely a trace was found.

This shows that the gastric juice attacks connective tissue much more intensely; that connective

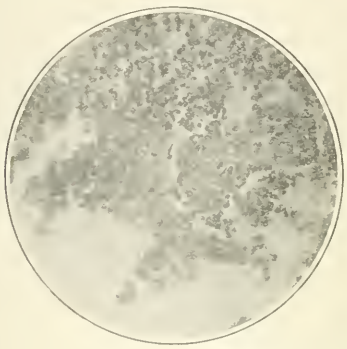

FIG. 3.—Thymus gland section; nuclei visible all over.

tissue may, however, also be digested by solutions of trypsin, although only very slowly.

This also coincides with the clinical observations of Lewinski.* The latter has described several cases of achylia, in which the examination of the feces according to Schmidt's method showed good connective tissue digestion. On the other hand, persons with normal stomach secretion were found to have a poor digestion of connective tissue.

The digestion of fish bones may be accomplished without the aid of stomach juice, as described in a former paper of mine and as may be seen from the table (Cases 1, 2, 3, 5, achylia with disappearance of fish bones).

As these food substances (connective tissue, catgut, fish bone) have not proved sufficiently reliable for the presence or absence of gastric juice, I tried other indicators. Of several substances that I used for this purpose (potassium permanganate thread, thread impregnated with stannous ferrocyanide ($Sn_3[Fe(CN)_6]_2$) and ferrous phosphate ($Fe_3(PO_4)_2$),

FIG. 4.—Thymus gland section after passing through the digestive tract of patient L.; nuclei almost all destroyed.

zinc sulphide, etc. Ultramarine blue has proven the most suitable. Ultramarine blue represents a blue pigment, which in the presence of HCl is dissolved with the evolution of H_2S gas, but is un-

*J. Lewinski. Sahlis' Desmoidprobe und Schmidt's Bendegehsprobe, *Münch. med. Woch.*, 1907, N. 9.

changed in alkaline or neutral media. Ultramarine blue would be an ideal indicator for HCl, if organic acids would not also dissolve it. They do this, however, although to a less degree than HCl, and for this reason ultramarine blue is not a positive indicator for HCl. Still I would like to report my experiments with ultramarine blue, as frequently the presence of HCl coincides with the disappearance of ultramarine.

The test was made in the following manner: A small quantity (0.01 gram) of ultramarine was placed into the thymus bag (which in this case was made of linen instead of gauze); thus the digestive capsule contained the usual six substances and ultramarine blue.

TABLE OF CASES IN WHICH ULTRAMARINE BLUE WAS USED.

16 cases with free HCl....ultramarine disappeared.
6 cases with free HCl.....ultramarine present.
3 cases of achylia gastrica....ultramarine present.
3 cases of achylia gastrica....ultramarine (trace) present.
1 case of achylia gastrica..ultramarine disappeared.
4 cases with unknown stomach secretion .....ultramarine present.

It is evident that ultramarine blue cannot be relied upon as an indicator for free HCl. It failed to dis-

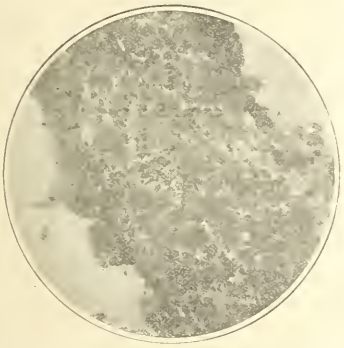

FIG. 5.—Thymus gland section after passing through the digestive tract of Mrs. McE., with achylia gastrica; numerous nuclei still unchanged.

appear six times although HCl was present, and once it disappeared entirely in a case of achylia gastrica.

The fact established by Schmidt, that nucleins are destroyed, not by the gastric but by the pancreatic juice, was also made the subject for experiment as follows:

I. March 8, 1907. A piece of raw thymus is placed into 5 c.c. of gastric filtrate (HCl + acidity 84) and kept at blood temperature in a test tube. After 24 hours one-quarter of thymus is present, the other parts have disintegrated. The connective tissue has disappeared, the nuclei are well preserved. Forty-eight hours later the nuclei are well preserved.

II. April 29, 1907. A small piece of raw thymus is kept at blood temperature in the following solutions: (*a*) in a solution of pancreon (0.3 to 5.0 water); (*b*) in a similar solution of pancreon with the addition of HCl (2-1000); (*c*) in a similar solution of pancreon, with the addition of lactic acid, (2-100). After 24 hours all the thymus pieces are unchanged; the nuclei are well preserved. After 48 hours macroscopically all the pieces unchanged; in (*a*) the nuclei have partially disappeared, in (*b*) and (*c*) they are well preserved.

III. May 2, 1907. A piece of raw thymus is kept at blood temperature in the following solutions: (*a*) in a trypsin solution (one part to three parts of water); (*b*) in a trypsin solution with the addition of HCl (2-1000); (*c*) in a trypsin solution with the addition of lactic acid (2-1000).

After 24 hours all the pieces look unchanged and the nuclei are well preserved; after 48 hours *a* feels more spongy and the nuclei have partially disappeared; *b* and *c* are unchanged and the nuclei are well preserved; after 72 hours the nuclei in *a* have almost entirely disappeared; in *b* and *c* they are well preserved.

These experiments show that Schmidt's opinion that pancreatic juice, and not gastric juice, digests the nuclei is correct.

In using the nucleus test Schmidt makes use of pieces of raw meat tied up in a silk bag. After recovering the latter in the stool, sections are made of the muscle, and these are examined microscopically for nuclei.

Instead of meat I have used thymus for the nucleus test, as this gland consists almost entirely of nuclei, and thus shows the nucleus digestion better. At first I used to have sections made from the remains of the thymus. As the examination consumed a good deal of time (1 to 2 days), I later simply made a smear preparation from the thymus direct and examined this for the presence of nuclei. Numerous comparisons between sections and smears have always given the same results. The latter method is therefore sufficient. I append a picture obtained by making a smear from the normal thymus (Fig. 1) and also the picture of a smear from a piece of thymus that has passed through the intestinal canal (Fig. 2).

I also add three illustrations from photographs of thymus sections: Fig. 3 represents the normal thymus; Fig. 4, thymus after passing through the intestinal canal of Z. (patient with cirrhosis of the liver and miliary tuberculosis); Fig. 5, thymus after passing the intestine of Mrs. McE. (achylia gastrica); in the latter there are numerous nuclei present.

Although the nucleus test is very interesting, still I do not think that the lack of pancreatic secretion can be diagnosed from the presence of nuclei. For patient McE. certainly had no disease of the pancreas, yet nuclear digestion was absent. In the case of Dr. C. (see table, Cases 103, 105), the nuclei were well preserved on one day, whereas later, shortly before death, the nuclei disappeared. In the case of a very grave lesion of the pancreas this would hardly be possible.

We may assume that occasionally, but very rarely, pancreatic juice, owing to the presence of other substances (perhaps HCl or organic acids, etc.) may be impeded in its action upon the nuclei. We can plainly see this in our experiment, when we add HCl and lactic acid to the trypsin. In Dr. C. such an explanation would probably hold good, because at the time when nuclear digestion was absent the patient had a normal gastric juice (HCl + acidity 56); later the acid was absent altogether, although nuclear digestion was present. Chronic jaundice existed in this case during the entire time the patient was under observation.

In conclusion I would like to say that the method of testing the digestive function of the intestinal canal by means of the bead string is very simple and handy and I feel it is time now that it should be made use of in the diagnosis and treatment of intestinal diseases.

SOME EXAMPLES OF CHEMICAL SYNTHESIS AS APPLIED IN THE PRODUCTION OF REMEDIAL AGENTS.

By JOHN W. WAINWRIGHT, M.D.,

NEW YORK.

Probably there is not another science which, since the middle of the last century, has undergone as radical a transformation as the practice of medicine and the closely related teachings of materia medica. This is not surprising, in regard to the latter, when we consider the remedial agents which were passed down from the days of antiquity and continued to be prescribed up to that period. With few exceptions, these remedies were so fearfully and wonderfully made that they could not withstand the sober investigations of a thoughtful observer for any length of time. Nevertheless a favorable change would hardly have taken place without the brilliant rise of physiology in the last decades. The works of Johannes Müller, Virchow, Dubois-Raymond, Ludwig, Billroth, Carpenter, Dalton, Foster, Flint, Kirke and others formed the basis of the teachings of the normal function of organs, and of cellular pathology, essentially contributing to the knowledge of the disturbances caused in the organs by disease. This recognition in its turn awakened the endeavor to counteract these disturbances, which had become thoroughly known, by means of appropriate remedies, with the idea that these remedies were to affect the diseased organ alone; as far as possible remaining indifferent to the rest of the organism. The possibility of finding bodies with these sharply defined specific properties had become less remote since chemistry had succeeded not only in the isolation and preparation of certain physiologically active substances occurring in plants, but also in the accurate determination of their chemical composition (morphine, quinine, atropine, hyoscyamine, etc.).

By further chemical research, more extensive information was obtained concerning certain substances which occur in the animal organism or are excreted by it. Thus, Rouelle discovered uric acid in the urine, and Wöhler prepared this substance synthetically a few years later, or in 1828. Since the synthetical preparation of organic substances from the elements had proved impossible up to that time, the prevailing opinion was that the chemical elements in living bodies were subject to other laws than those of the so-called inanimate realm. It was assumed that organic substances were formed in the organism only under the influence of a special "vital force," and that their artificial preparation, after the manner of inorganic substances, would not prove feasible.

Wöhler's discovery was of the utmost significance in so far as it served to contradict and refute the assumption of a special force concerned in the formation of organic bodies. It furnished the demonstration of the fact that the structure of inorganic bodies does not essentially differ from that of organic bodies; that the properties of the organic compounds are based only upon the character of their essential constituent, carbon; and that all the chemical compounds produced by the vital processes of plants and animals may be prepared by synthesis, or in an artificial manner, from the individual elements.

Based upon these facts, and after the chemical composition of the majority of bodies serving as remedial agents had been determined, it became the endeavor of chemists, in conjunction with pharmacologists, to discover the origin and mode of action of individual remedies. For this purpose, it was necessary to proceed to the chemical decomposition of the known remedial agents in order to determine to which part of the molecule the specific effect is due. These studies of the action and analysis of products served in their turn as a guide for the construction of new remedial agents, to be prepared by way of synthesis, since proof was furnished to the effect that there invariably exists an absolutely definite connection between the constitution of a given chemical body and its action. Certain modifications in the human organism, as for instance the diminution of a febrile rise of temperature, depend upon the presence of definite groups of atoms in the frequently highly complicated molecule of the agent employed. Accordingly it was found that the employment of a remedial agent for medical purposes means the utilization of definite groups occurring in its molecule; and further, that it is not always necessary for the entire molecule of individual chemical substances found in nature, to participate in the action. When constructing a chemical body which is to serve as a remedial agent, we provide only efficient groupings within it, or we may add to other groups in order to weaken the overstrong action of the fundamental substance. In the remedial agents found in nature, which are not constructed for the purpose of serving as remedial agents, but whose chemical structure, due to certain physiological actions of plant life, is accidentally available for therapeutic purposes, whereas the entire body as such may participate in the action, the pharmacological effect in the majority of cases is probably dependent only upon a portion of the molecule. It follows that it is by no means necessary to produce by way of synthesis precisely the body occurring in nature, but that it suffices to obtain substances, the action of which is identical with that of the natural ones, or even surpasses it, if possible, without, however, giving rise to untoward side effects. With increasing experience as to the action of individual chemical groups, the path became more clearly outlined for the steps of chemists and pharmacologists towards the systematic construction; in other words, the synthetic preparation of new bodies having pharmacologically valuable properties, and destined to serve as remedial agents. Synthetic chemistry in particular was expected to profit by the pharmacological study of the numerous classes of substances, in such a way as to prepare and discover new bodies, possessing new therapeutical properties not supplied by nature. It is worthy of note that most people, laymen and physicians alike, do not possess the proper perception of what is meant by synthetic remedies, and they often indulge in erroneous ideas concerning their preparation. Whenever conversation turns upon the origin of a new synthetically prepared product, brief comments are generally heard to the effect that it is an anilin derivative, or it is obtained from coal-tar. These summary remarks lead to the conclusion that there can hardly be anything more simple on earth than the synthetic preparation of remedial agents, since all that has to be done is either slightly to modify anilin by some chemical reaction, or to fish the desired substance in some way from a barrel of coal-tar. This naturally leads to the belief that these products ought to be enormously cheap, since they were obtained from easily accessible materials, or even from refuse products.

This view is absolutely erroneous, however. The majority of synthetically prepared remedial agents have nothing in common with either anilin or coal-tar, not even when these substances have been employed in the preparation of some one agent, for the reason that as a rule they have undergone such profound changes in regard to their constitution and properties, through chemical processes of transform-

ation, that the resulting terminal product can no longer be designated as an anilin derivative or as a product obtained from coal-tar, in the ordinary sense of the word.

The amount of mental and manual labor, as well as the perseverance, required for the preparation of a practically useful synthetic remedy can really be estimated at their true value by the professional man only. In order to obtain practically applicable products, thorough collaboration is required on the part of the chemist, the pharmacologist, and the clinician. Neither is it enough for the chemist to prepare a single product, for his work must take into consideration all the possible combinations, and he must build up all sorts of preparations, since sometimes an apparently insignificant change in the position of the atomic groups towards each other, or the exchange of one such group for another, may assume a decisive importance for the practical applicability of the substance.

The pharmacologist in his turn has to test the substances prepared by the chemist, in regard to their therapeutic applicability, by means of animal experiments. This test, however, must not stop at the determination of the effect upon individual organs exerted by these manifold bodies, the chemical constitution of which sometimes differs very slightly; but the individual bodies must further be compared with each other and with other well-known remedies, in regard to their action. Only the most minute comparative examinations permit the selection of the substance, the clinical examination of which holds out the best prospects of success. These pharmacological experiments do not require much time, but they are a source of considerable expense, because investigations of this kind can be carried out only in well-equipped institutions, which are provided with all sorts of instruments and apparatus. It is only after the pharmacological examination of a given chemical substance has furnished definite data as to its possessing new therapeutically valuable properties, or at least certain advantages over similar older remedies, that this particular substance can be passed on to clinical examination.

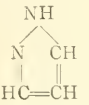
Clinical experiments with a new remedial agent in their turn must extend over a considerable number of carefully selected cases. Neither is it possible to reach a conclusive estimate as to the applicability of the preparation before the end of a prolonged period of time, 1 to 1½ years. In the majority of cases, it follows from the clinical experiments that the remedy after all does not behave in the human organism as should have been expected from the theoretical considerations and preliminary tests, and that its introduction into practice must accordingly be refrained from.

Although under such conditions the tedious and expensive work of the chemist and pharmacologist has not proved remunerative, it has nevertheless not been entirely in vain, since it has served to contribute to our knowledge and experience in the field of materia medica, and has shown how to avoid future failure.

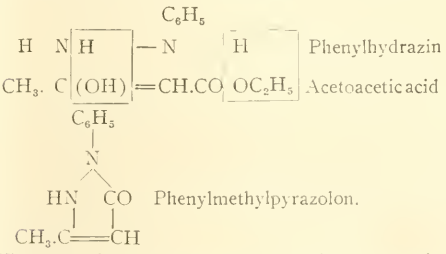
The above reflections, which suggest that the preparation of useful synthetic medicinal products is by no means so easy as is generally assumed, will be supplemented by some typical examples illustrating the synthetical course of a few of the best known remedial agents:

We will begin with the antipyretics. These fever-reducing agents are also analgesics; among the most prominent of them are antipyrin, acetanilid, phenacetin, lactophenin, etc. As antipyrin is the oldest of these products and perhaps more generally known and used by the physician, we will use it as an illustration, the proceeding being for the several preparations much alike.

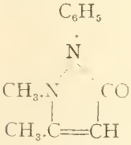
The specific antipyretic action of quinine caused Filehne to investigate the physiological action of antipyrin, as prepared by Knorr, which had originally been supposed to possess a constitution similar to that of quinine. This view was found to be erroneous, however, and is explained only by the incorrect interpretation prevailing at that period, in regard to the structure of quinine. Knorr assumed the body discovered by him to be a dimethyloxyquinidin. The physiological effect of antipyrin certainly favored the assumption that a body which was chemically analogous to quinine had been produced by way of synthesis. Later on, however, Knorr himself was enabled to show that his idea concerning the constitution of antipyrin had been erroneous, this constitution being actually based upon a new ring, the pyrazol-nucleus.



Basic substances for the preparation of antipyrin are benzol on the one hand, and acetic acid on the other. The benzol is converted into nitrobenzol by the action of nitric acid, and from the nitrobenzol anilin is obtained through treatment with reducing agents, such as iron and hydrochloric acid. Diazobenzol is obtained from anilin by means of nitric acid, and in its turn is reduced to phenylhydrazin. The acetic acid serves to prepare acetic-acid-ethyl-ester from which aceto-acetic acid ester is obtained by the action of metallic sodium. The condensation of the phenylhydrazin with the aceto-acetic-acid results in the production of a new body, phenyl-methyl-pyrazolon, through the splitting off of a molecule each of water and alcohol:



When one of the hydrogen atoms at the nitrogen is substituted by the methyl group, however, through treatment with methyl iodide, the result is phenyldimethylpyrazolon:



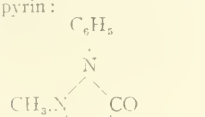
Antipyrin is known to possess antipyretic properties. This apyrexia sets in without the phenomena of collapse, and persists for a long time. Although anilin has entered into the preparation of antipyrin, the latter does not cause any damage of the blood pigment, as is frequently observed under the employment of direct anilin derivatives, such as for instance acetanilid.

Like all the febrifuges hitherto produced, antipyrin does not possess the specific effect of quinine upon malaria. On the other hand, Germain Sée

first pointed out a property of antipyrin, in which it far exceeds quinine, the typical febrifuge, namely its remarkable action as a nervine. It not only possesses the property of producing local anesthesia, but neuralgic pains may be aborted by its internal administration. According to Hénocque, hemorrhages subside more rapidly when the wound is treated with antipyrin than under the employment of chloride of iron or ergotin. The same investigator showed that antipyrin causes contraction of the vessels, retraction of the tissues, and coagulation of the blood. The fact that phenyl (mono) methylpyrazolon, the intermediate product in the preparation of antipyrin, possesses no particular febrifuge effect, is of especial interest because of the relation between its constitution and physiological action. The characteristic physiological action of antipyrin appears only through the introduction of the methyl group at the nitrogen. It is also very remarkable that only those bodies which are derived from pyrazolon have an antipyretic effect, while the isopyrazolons are poisonous.

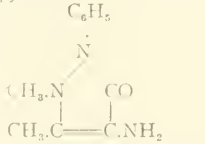
It has been seen that antipyrin is characterized as containing in its molecule the group NCH_3, which is also found in morphine and all the natural alkaloids having a strong narcotic action. The successful introduction, by means of substitution, of this group or one chemically related to it, into the antipyrin molecule, could but be expected to result in a remedy superior to antipyrin. Among compounds prepared according to this idea, dimethylamido-pyrazolon was prepared by Stolz in 1803.

It differs from antipyrin by the hydrogen atom in the pyrazolon ring being replaced by the group $N(CH_3)_2$, thus representing the dimethyl-amido-antipyrin:

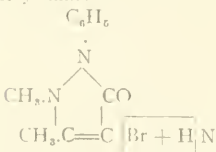


The substitution was made at the pyrazolon ring rather than the benzol ring, because the higher homologues of antipyrin, for instance tolipyrin, the preparation of which starts, not from benzol, but from toluol, possess no advantage to antipyrin.

Dimethyl-amido-pyrazolon (pyramidon) is obtained by allowing nitric acid to act upon antipyrin and then reducing the nitroso-antipyrin thus obtained. This results in the production of amido-antipyrin.



The amido-antipyrin is methylated into dimethylamido-antipyrin by means of methyl iodid, or the antipyrin is converted into brom-antipyrin by means of bromin. The brom-antipyrin is then heated with dimethylamin:

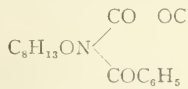


Phenacetin, phenocoll hydrochloride, and lactophenin differ but slightly in their chemical construction, phenacetin being an acetate of para-amido-phenatol, having the formula $C_6H_4(OC_2H_5).NH.(CH_3CO = C_{10}N_{13}NO_2)$. In lactophenin the acetic acid group is replaced by a lactic acid group. It has the formula $C_6H_4(OC_2H_5)$ $(HH.CH_3.CHOH.CO = C_{11}H_{15}NO_3)$. Phenocoll is represented thus: $C_6H_4.OC_2H_5NH(CH_2NH_2CO)HCl = C_{10}H_{14}O_2N_2HCl$.

The synthesis of these several products is quite similar to that of others of like character.

We will next take up the local anesthetics, and first give the chemistry of cocaine, following with a brief description of its substitutes made through chemical synthesis.

Together with other alkaloids cocaine is found in the leaves of erythroxylon coca, being as to its chemical constitution the methyl ester of benzoyl-ecgonin.



By means of various chemical reactions, cocaine may be split up into ecgonin, benzoic acid, and methyl alcohol; from these substances it may be reconstructed by converting the ecgonin, which has the properties of an acid, into the methylester, by means of methyl alcohol and hydrochloric acid, the methylester being benzoylated with benzoic acid anhydrid; or the ecgonin may be bonzoylated in the first place, after which the benzoyl-ecgonin is converted into the methylester. Neither ecgonin, its methylester, nor benzoyl-ecgonin presents an anesthetic action, this property appearing only in the benzolated ester of ecgonin. From the alkaloids contained in the coca leaves, in addition to cocaine, ecgonin may be obtained by means of chemical separation, the ecgonin being then synthetically converted into cocaine, so that ultimately more cocaine is obtained from the coca leaves than was originally contained in them as such.

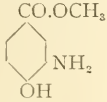
Among the decomposition products of cocaine, the methyl alcohol and the benzoic acid are readily accessible, but the more highly complicated ecgonin can be obtained synthetically only by a very difficult and devious method, so that synthetic cocaine cannot be prepared at remunerative rates. It is not only the presence of the benzoyl group which is required for the occurrence of the cocaine action; this is dependent upon the position and linkage of the hydroxyl and carboxyl groups.

The plainly evident and carefully studied connection between the constitution and the action of cocaine, and the importance which it had acquired in surgery, induced chemists to prepare other bodies having an analogous action, upon the basis of actual results. There were several circumstances which prompted investigation in this direction. On the one hand, the price of cocaine was and still remains a very potent factor, largely due to the manner of its production; and, on the other, professional experience promptly showed that we are dealing with a highly poisonous body, the dangerous character of which is further increased by the fact that a number of otherwise perfectly healthy individuals are particularly sensitive and possess a distinct idiosyncrasy towards cocaine. The systematic attempts to obtain useful substitutes for cocaine were based upon the accurately known composition of this body. As mentioned above, the benzoyl remnant in the cocaine (C_6H_5CO) has been found essential for the production of local anesthesia, since the cocaine lost this effect as soon as this remnant had been split off, and *vice versa*, certain bodies inefficient in them-

selves acquired the faculty of acting as local anesthetics, as soon as benzoyl had been introduced into them synthetically.

Einhorn and Heinz examined a large number of benzoylated compounds, including the benzoylated ester of the amido-benzoic acids, which in part presented the desired results up to a certain degree. Upon close inspection, however, it was found that the benzoyl remnant was of no importance in these bodies, for the nonbenzolated esters of the amido-benzoic acids in themselves were found to possess the local anesthetic effect to a far greater degree.

The m-amido-benzoic-acid-methyl-ester (orthoform) is obtained by first introducing carbonic acid into phenol, which results in the production of p-oxybenzoic acid (isomer of salicylic acid). Through the action of nitric acid, this is converted into m-nitro-p-oxybenzoic acid, from which the m-nitro-p-oxybenzoic-acid methyl-ester is prepared by means of methyl alcohol. From the latter, through treatment with reducing agents, the m-amido-p-oxybenzoic-acid methyl-ester (orthoform) is finally obtained, with the following formula of constitution:



The synthetic preparation of para-amido-benzoyl-diethyl-amino-ethanol-monohydrochlorate, known as novocain, starts with p-nitrobenzoic acid, which is converted into p-nitro-benzoyl chlorid, this being allowed to act upon diethyl-amino-ethanol $HOCH_2CH_2.N.(C_2H_5)_2$. This results in the production of p-nitro-benzoyl-diethyl-amino-ethanol through the action of zinc and hydrochloric acid.

In order to obtain the basic constituent of novocain, the diethyl-amnio-ethanol, ethyln-bromid is boiled with water and potassium carbonate, resulting in the production of ethyln-glycoll, which is distilled in flowing hydrochloric acid, converting it into ethyln-chlorhydrin $HOCH_2CH_2Cl$. From the latter diethyl-amino-ethanol is obtained by heating with diethylamin.

Diethylamin is obtained from diethylanilin $C_6H_5N(C_2H_5)_2$, nitric acid being allowed to act upon it, which results in the production of p-nitroso-diethyl-anilin $NOC_6H_4N(C_2H_5)_2$. When the latter is boiled with caustic soda, there results diethyl-amin $HN(C_2H_5)_2$, which is distilled over, while p-nitroso-phenol is left behind.

Benzoyl-ethyl-tetramethyl-diamino-propan hydrochlorid (alypin) is made by the action of dichlor-acetone on ethyl-magnesium bromid from which ethyl-dichlor-hydrin is obtained. From this through the action of dimethylamin, ethyl-tetramethyl-diamino-propanol is produced. The product is treated with benzoyl chlorid and neutralized with hydrochloric acid to form the hydrochloride.

Beta-eucain, the trimethyl-benzoyl-hydroxy-piperidin; stovain, benzoyl-ethyl-dimethyl-amino-propanol hydrochlorid, and other like substances, are synthetically prepared.

In addition to the antipyretics and analgesics, anesthetics, etc., here mentioned, numerous antiseptics, astringents, antilithics, hypnotics, antispasmodics, etc., are prepared in the chemists' laboratory, many of them praiseworthy remedies, but unfortunately most of them of minor importance to the physician.

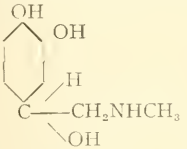
The active principles of the suprarenal will be mentioned in conclusion.

It has been shown by recent investigations on the part of physiological chemists that the suprarenal bodies contain a substance possessing to a high degree the power of increasing blood pressure. This effect is referable in the first place to a vascular constriction caused by the substance, and this accounts at the same time for its marked astringent and hemostatic properties.

The active substance of the suprarenal bodies, which was first isolated by J. J. Abel, of Johns Hopkins, was not a commercial product. Later, Aldrich and Takamine, each working independently of the other, were able to obtain the substance in a marketable shape, which they named adrenalin. Von Fürst in Germany arrived at like results, designating his product suprarenin. Like substances, suprarenalin, adnephrin, adrenin, etc., have been made, all from the gland.

These preparations found such extensive application in the various branches of medicine that probably by this time every physician is familiar with them from personal experience. No other remedy has excited the interest of physicians, pharmacologists, physiologists, and chemists to the same degree, from its very first appearance as suprarenin, the proper chemical designation for the active principle; therefore the most thorough investigations have been conducted for the purpose of determining its chemistry.

After the views of investigators had for a long time been considerably at variance, experiments led to conclusions that suprarenin has the following formula of constitution:



This furnished the basis for the synthetical construction of suprarenin. After many chemists had in vain endeavored to obtain it, this was at last accomplished by Dr. Stolz. His discovery ended the long series of purposeful painstaking labors, and with it chemical industry has won a triumph in the field of medical synthesis, which seems to be unique at the present time.

The individual phases of the synthetical preparation of suprarenin are as follows: First, brenzcatechin is obtained from benzol or phenol by converting them into phenol sulfo acid, and blending this with potassium. When the brenzcatechin is heated with chloracetic acid there results the production of chloraceto-brenzcatechin $HO_2C_6H_3.COCH_2.Cl$. When methylamin is allowed to act upon this body, the methyl-amino-aceto-brenzcatechin is obtained, $(HO)_2C_6H_3COCH_2NHCH_3$, a substance having a certain external resemblance to suprarenin and possessing a weak action upon the rise of blood pressure. It differs from suprarenin only by containing two atoms of hydrogen less than that substance. By suitable treatment with reducing agents, the methyl-amino-aceto-brenzcatechin may be converted into the o-dioxy-phenyl-ethanol-methyl-amin $(HO)_2C_6H_3CHOHCH_2NHCH_3$, which is identical in its chemical properties with natural suprarenin. Like this, it contains an asymmetric carbon atom, but is optically inactive, since it constitutes the dextrorotatory form of dioxy-phenyl-ethanol-methyl-amin; whereas natural suprarenin is levorotatory. In its physiological action the synthetical compound differs neither qualitatively nor quantitatively from suprarenin obtained from the suprarenal bodies.

These explanations, which are for the purpose of giving an idea of the course of medical synthesis, may possibly contribute towards the dissipation of

the uncalled-for prejudice prevailing against the employment of synthetic remedies. It certainly cannot be denied that chemistry, in conjunction with pharmacology, has supplied the physician with many useful medical agents which he would hardly care to lose from his stock of remedies.

Notwithstanding the fact that the large chemical manufacturers who work upon a serious scientific basis will put a new medical agent upon the market only after the pharmacological, physiological, and clinical tests, conducted on the part of authorities, have demonstrated that the offering of the new remedy corresponds to the actual need of modern therapeutics, it still remains the physician's task to consider these remedies as they appear from the chemico-pharmacological point of view. He will then be enabled to estimate whether the new remedy fills a gap in his stock of remedies, or whether it represents merely an imitation of familiar medicinal agents, of which it may be predicted that no new therapeutic effect is to be obtained.

The extension of his pharmacological knowledge will enable the physician to distinguish what is new and good from what is new and superfluous. Under these conditions, he will not lay both heedlessly aside, as is often done at present, but he will make use of the new and the good for the benefit of his patients, as well as for his own renown.

To have accomplished a synthesis of a principle which is represented only in the glands of animals is to be regarded as but a little short of the marvelous, or, as it would have been considered but a decade or two since, miraculous. Having succeeded in producing in the laboratory this principle, why not a synthetic thyroidin and active principles of other glands? And why should we stop there? The secrets hitherto concealed in Nature's workshop are being wrested from her, and we are warranted by past achievements in predicting further developments even more marvelous. The veil which has hitherto hidden the works of Nature has been rent, thus allowing those near to observe her methods. There will be no jealousy or selfish desire to possess alone the secrets of this hitherto unapproachable workshop. Apprentices are to be had, eager, earnest workmen, who will give their lives to the work, and, unorthodox and heretical as it may sound, it is nevertheless true that these same earnest men will do the work better than it has hitherto been done. It is for us to stand afar off and view the work that is being done, see the edifice reared which shall blaze the way for future generations, as did the works of Levoisier and Dalton. We may admire and cheer the workman, or criticise and demean him, but it matters not in either event: the structure will be completed. The antagonism to scientific achievements which has been apparent since the days of Galileo will only serve to make the truth more resplendent.

127 West Eighty-third Street

SOME PHASES OF HOSPITAL PROGRESS*

By S. S. GOLDWATER, M.D.,

NEW YORK

COMMISSIONER OF THE MUNICIPAL HOSPITALS

It is the function of the Committee on Hospital Progress to report history in the making. The difficulties of the task will be readily appreciated by anyone who has tried to keep in touch with hospital work in this country during the past year, and also will endeavor to select from the mass of observed or recorded facts those which are in organic relation to the development of the whole hospital body.

In the preparation of the report on hospital progress it is the function of other members of the committee to deal with the definitely outlined fields of hospital construction, medical organization and medical education, and the training of nurses. The duty of reporting on the more general subjects of hospital efficiency and the economics of administration rests upon me, and in presenting these subjects I shall endeavor to include such facts or occurrences as fall within the period under observation and appear to be capable of affecting the efficiency of hospitals generally. Such facts are:

(a) The growth of hospital extension work (comprising under this term all those branches of hospital work beyond the wards which have their common root in the newer conception of the hospital patient as a social unit).

(b) The growth of cooperation among organized medical charities, including the formation of permanent hospital leagues, as well as the organization of looser associations of hospital workers, and the study of hospital needs of given districts as a means of enabling the hospitals of such districts to understand the character of the needs which, collectively, they should satisfy.

(c) The approach toward that uniform method of accounting which ultimately will do so much for the enlightenment and guidance of hospital workers and hospital supporters.

(d) The attempt to establish a proper balance between municipalities or the public purse and those voluntary hospitals which by their work call forth generous private gifts and thereby lighten the burden of municipal taxation.

(e) The recognition of the personal and social needs of hospital employees, and the beginning of welfare work in their behalf.

(f) The establishment of the first chair of Hospital Economics designed for the training and instruction of hospital superintendents in the principles of their work.

The Growth of Hospital Extension Work.—The time is still within the recollection of the youngest hospital workers when the words "cured," "improved," and "unimproved" ended the story of the hospital's beneficence in the case of every patient who left the hospital alive. To-day the most progressive hospitals frankly accept a larger measure of responsibility and are ready either by the freer employment of their own resources or by bringing into play the resources of others, to extend their usefulness into the homes of patients whose illness has reduced dependents to a condition of destitution, and to assist the patients themselves, when ready for discharge, toward a return to social or industrial activity.

So far as the special needs of convalescents are concerned, it may be said that these needs, though as yet but sparingly provided for, are now at least everywhere recognized. A hopeful sign is the great emphasis laid upon the special claims of the convalescent in a large number of recent hospital reports—for the recognition of a need is the first step toward getting it attended to.

The president of the Presbyterian Hospital of New York makes the interesting suggestion that hospitals unite for the establishment of convalescent branches in common. He says: "If adequate provision were made for convalescents in the country, permanent cure would be far more cer-

*Report of the Committee on Hospital Progress, presented at the Ninth Annual Meeting of the American Hospital Association, Chicago, Ill., September 18, 1907.

tain and the length of stay of patients in our city hospitals could be so much diminished as to greatly increase hospital accommodation, without any increase in hospital plant. It may be that some plan of cooperation could be worked out which would give our hospitals this resource in common at a minimum cost, and thus not only increase their working capacity but also probably make a considerable reduction in the daily cost per patient."

To an appreciable but insufficient extent the needs of convalescents discharged from New York hospitals have been met by the establishment of the Loeb Memorial Home for Convalescents, caring for about one hundred patients, at East View, Westchester county, N. Y., and by the use as a convalescent hospital for women and children during the winter months of the Seaside Hospital of St. John's Guild, at New Dorp, S. I., a hospital formerly carried on only during the summer months for the care of sick children and infants.

Of interest in this connection is the confirmation of the reports concerning the Burke Foundation, the trustees of which, on the death of John Masterson Burke, a nonagenarian, will assume control of a fund of four million dollars, which is to be used largely in the interest of hospital convalescents.

A further event of great significance to the hospitals of New York is the establishment of the new Seaside Park by the City of New York—a tract of some four hundred acres of ocean beach stretching for nearly a mile along the south shore of Long Island, within the limits of which sites are to be set aside at nominal rental, on long leasehold, for the use of charitable societies wishing to build convalescent hospitals. For the guidance of other municipalities which may wish to emulate the example of the City of New York, I quote the following section of the bill under which the new park has been established: "With the approval of the Sinking Fund Commissioners, the Board of Estimate and Apportionment shall have the power whenever it shall deem it of public interest, to withdraw from the jurisdiction of the Park Board such portion or portions of said property, and to allow the use of said portion or portions so withdrawn for a period of thirty years, with the privilege of renewal for a period of twenty years, by any charitable or benevolent society of the City of New York that will erect a convalescent hospital or hospitals and provide for the care therein of residents of the City of New York, provided such building or buildings are so located and constructed as in the judgment of the Board of Estimate and Apportionment shall not disfigure said park or interfere with the purposes of public use and recreation.

For the long-neglected convalescents a brighter day seems to be dawning—a time in which his needs will be studied and recognized and in which his course toward recovery will be safeguarded and assured. In the meantime, while waiting for convalescent homes and branch hospitals, what can we do for the individual patient which we do not yet do? At least we can make his acquaintance and try to satisfy his individual needs. The introduction of a friendly visitor or social nurse into the wards of Bellevue Hospital a year ago was the first attempt to do this work in a large general hospital; the example of the progressive administration which has done so much for Bellevue has since been followed by Mount Sinai and other institutions. The advent of the social nurse has been widely noticed and everywhere approved. "Nothing can signalize more cheeringly the growing humanity of our public institutions," is the comment of an editorial writer in *Charities*.

In the opinion of Dr. Samuel T. Armstrong, General Medical Superintendent of Bellevue and Allied Hospitals, "the experiment (of having a nurse visit each patient admitted to the wards to learn whether it is necessary or practicable to refer the patient or the destitute family of the patient to some of the many charitable organizations of the city) has proved quite successful. Daily the nurse sees each new patient and by a tactful and brief interview learns whether anything more than medical or surgical treatment is needed to benefit the patient, and if further help is advisable she communicates by letter or telephone, and sometimes by personal interview, with the particular agency that is best fitted to aid. This has resulted in sending convalescents to country homes, in securing provisions for destitute families, in obtaining employment for those discharged from treatment who are without funds, in uniting separated families, in the further treatment of alcoholics, and in much other beneficence."

While welfare work is thus gaining its first foothold in large general hospitals, it is only just to say that for some years a number of special hospitals have been carrying on similar work. In March, 1906, the Ladies' Auxiliary of the Lying-In Hospital of the City of New York announced that during the preceding year 323 destitute and homeless cases had been reported through its In-Patient Committee, which committee maintained during the year a friendly visitor in the wards. There could be no broader policy than that of this committee, whose endeavor it is to see "that no woman should leave the hospital without receiving such help as she may require." The self-appointed work of this committee is "to find homes for those who are homeless, to provide clothes, food, and fuel when necessary, to make arrangements for placing the infant in a day nursery should the mother have to go out to work by the day, and in every way to give such assistance as is necessary and wise in each individual case."

Further examples of extension work by hospital and dispensary are afforded by the activities of paid and volunteer workers in connection with the Out-Patient Department of the Massachusetts General Hospital; by the growing work of the Department of Visiting Nurses of Vanderbilt Clinic; by the visiting nursing conducted by the Presbyterian Hospital and Dispensary of New York, and by the home visiting of the medical and nursing staff of the Babies' Hospital.*

The Movement Toward Cooperation.—The past year has witnessed the organization of several new associations of hospitals and hospital workers, as well as the further development of the work of associations previously in existence.

On April 1, 1907, forty-nine hospital superintendents attended the meeting at Toronto, Ontario, from which sprang the new Canadian Hospital Association, with plan and purpose similar to those of the American Hospital Association.

On May 16, 1907, the West Virginia Hospital Association held its first annual meeting at Hunting-

*I cannot refrain from calling attention here to the excellent and, so far as I know, the first comprehensive published statement of the social aspects of hospital work from a theoretical standpoint, an essay from the pen of a former associate of the present writer in the work of Mt. Sinai Hospital—Sidney E. Goldstein. This article appeared in *Charities*, on May 4 and 18, 1907, under the caption, "The Social Function of the Hospital."

ton, W. Va.; a prominent place in its program was accorded to "Uniformity and Cooperation Among Hospitals."

In October, 1906, the Hospital Association of Philadelphia, the mother of local hospital associations in this country, gave evidence of its broad social spirit by appointing a committee to confer with a similar committee of the Society for the Prevention of Social Diseases, to consider subjects affecting the public health.

Since 1902 the superintendents of the State charitable institutions of New York have met several times each year at the office of the Fiscal Supervisor of State Charities, for the purpose of considering joint contracts for supplies.

In Michigan a joint meeting of the boards of trustees of the five State hospitals for the insane is held twice each year. The joint board, as it is called, agrees upon a scale of salaries and a per capita allowance for the different hospitals according to their different needs.

In Colorado the president of the State Medical Society, at the last annual convention of that body, announced that letters had been addressed to each of the principal hospitals in Denver suggesting that a Board of Hospital Councilors be created by the appointment of one or more representatives from each hospital, and that this board be asked to devise means to control common hospital abuses.

The Hospital Conference of the City of New York, aiming to increase its efficiency, at the close of 1906 appointed a permanent Committee of Investigation, subdivided into smaller committees for the special investigation of the following subjects: (a) Hospital expenditure; (b) uniform accounting; (c) State inspection and municipal aid; (d) the distribution of hospitals and of hospital beds in relation to the needs of the community; (e) ambulance service; (f) paying patients; (g) treatment of patients in their own homes; (h) cooperation of hospitals with each other and with other relief agencies (i) dispensaries; (j) medical organization and medical education.

Without attempting to appraise the value of each step and incident in the cooperative movement, it must be acknowledged that the joint activities just enumerated show that a widespread cooperative movement exists. Evidently there is growing up among hospital workers something akin to the class consciousness of the industrial workingman, but the consciousness of a class which aims to develop a solidarity based upon no desire of group advancement, but upon the common wish to work more effectively for the health and happiness of others. And there is no doubt that notable gains will spring from the growing cooperative movement. But if the efficiency of any group of hospitals is to be enhanced by cooperation, the ground must first be prepared by a study of the hospital needs of the community to which the hospitals belong. This is recognized by the City of New York, which wishes to improve and if possible to perfect its municipal hospital service (the condition of which at present is quite as chaotic as that of the voluntary hospital service of the city) and which hopes that valuable results will follow from the investigation that is now being conducted by the Hospital Commission appointed by Mayor McClellan in 1906. The Mayor's commission was created for the avowed purpose of devising a comprehensive plan for the reorganization of the municipal hospital system. The commission has wisely decided that before formulating its recommendations it will ask for information on hospital administration from the mayors of all cities in America and Europe having a population of over 100,000.

While the Mayor's commission is studying the hospital needs of the city from the standpoint of the municipality, an investigation of the present and future hospital needs of the city is being privataly conducted by the State Charities Aid Association, which has already to its credit many valuable services rendered to the hospital and other charitable institutions of the city and State of New York. A study of the medical charities of Greater New York has also been made during the year by Miss Lattimore, a student in the New York School of Philanthropy, whose observations were summarized in the *New York State Journal of Medicine* during the earlier months of the year.

The dearth of reliable facts concerning hospitals is well known and applies to many municipalities besides New York. It is proper, therefore, to repeat the suggestion, made by Miss Aikens last year, that our own Association might in the course of time, when its financial condition and numerical support warrant, undertake the establishment of a central bureau of hospital statistics for the collection of data of common interest to the various communities and for the development of exact and useful methods of tabulating statistics of hospital administration.

Uniform Accounting.—The advantages of uniform accounting itself, far from spreading with the rapidity of wildfire, creeps along at snail's pace. Its active supporters are, unfortunately, but a handful, and their painstaking and convincing work deserves stronger countenance. The uniform system proposed by four New York hospitals has now been officially endorsed both by the American Hospital Association and by the Hospital Conference of the City of New York. To hasten its adoption, however, there seems to be need of some such new stimulus as outspoken public criticism, a weapon which can be wielded with good effect only by a powerful and respected press. It is my conviction that the welfare of hospitals would be promoted by the publication, in a fearless and independent organ of hospital progress and of administrative efficiency in philanthropic work, of a critical analysis of the reports of hospitals claiming public support. If the weakness and insufficiency (I will not say the disingenuousness) of some of these reports were brought to the notice of the public, the hospital managers concerned might be induced to see the wisdom of rendering a fuller and more satisfactory account of their stewardship. In the meantime, the movement toward uniformity can be aided by the prompt consideration and the emphatic endorsement of the uniform system (already sanctioned by this Association) by State and local associations and conferences wherever and whenever organized.

State and Municipal Aid to Private Hospitals.—The long-expected increase in the per capita per diem rate granted to voluntary hospitals caring for charity patients in New York City has at length been granted. Such hospitals now obtain, subject to strict regulations, an allowance of 70 cents per day for adult medical cases, 90 cents per day for adult surgical cases, and 45 cents per day for children. (The new rates average about 14 per cent. more than those which previously prevailed.) A comparison of these rates with the daily cost of maintaining ward patients in the hospitals affected, shows that while the municipal government of the City of New York is willing to cooperate with

private hospitals which relieve it of the necessity of caring for a considerable number of charity cases, its appropriations toward the support of such institutions are eminently judicious and are by no means calculated to relieve the supporters of such hospitals of their voluntarily assumed obligations. An analysis of the work done by thirty-nine hospitals connected with the Hospital Saturday and Sunday Association for the fiscal year ending September 30, 1905, shows that 969,897 days of free treatment were given by these hospitals during the period named, and that the current expenditures of the hospitals, for maintenance alone, amounted to over $2,600,000. The appropriations from the City Treasury toward the support of these hospitals during the same period was only $293,000.*

New York is not the only section of the country in which the appropriation of public funds for the partial support of hospitals privately managed is now sanctioned by public opinion and by law. A comparison of the methods followed in making such appropriations, therefore, will not be out of place. The two principal methods according to which such appropriations are made, are the lump sum subsidy system, exemplified in the practice of the Commonwealth of Pennsylvania, and the per capita contract system, one form of which prevails in the City of New York. (The lump sum subsidy system formerly prevailed also in the District of Columbia, but the contract system has since been adopted in lieu of the older method, with results which appear to be entirely satisfactory to the District Board of Charities.)

During the years 1903 to 1905 (appropriations being made for two years at a time) the State of Pennsylvania set aside for the support of one hundred and seventy-six private charitable institutions the sum of $4,657,000, equal to $2,328,500 per year. This sum was distributed among the various beneficiaries without any restrictive or guiding statutory provisions.

Such appropriations are made in Pennsylvania by act of legislature, and theoretically the sums set aside are supposed to bear some relation to the needs of the institutions concerned and to the amount of work done or to be done by such institutions according to the opinion of the State Board of Charities; in practice no such relation exists. It is customary for institutions seeking aid to petition the State Board of Charities, and subsequently, by their representatives, to appear before that Board to support their claims by argument and for the purpose of furnishing any further information the Board may desire. In a report made to the Hospital Association of Philadelphia, from which I shall take the liberty to quote, Mr. Firth explains that "the petitioners appear in considerable numbers and are often subject to long delays before they are reached, with not much possibility of the Board being able to give any one petitioner a full and detailed hearing. Upon no systematic plan, so far as is known, the board decides upon the amount it will recommend that the Legislature shall grant to each applicant. The applicants then move upon Harrisburg. They interview and seek to bring friendly influence to bear upon members of the Legislature to induce favorable action upon their petitions. The Legislature may, and does, appropriate to other institutions and in other amounts than those recommended by the Board of Public Charities. The unequal and seemingly inequitable distribution of public funds that always results from the practice now governing has caused many good citizens to condemn the entire policy of the State and to advocate confining the use of State funds to the support of institutions owned and operated by the State."

That inequality in the distribution of hospital funds to the hospitals of Pennsylvania does exist is shown by the following figures, taken from recent reports of four Pennsylvania hospitals chosen at random:

Total days free treatment of ward patients.	Estimated cost of treating free patients.	State appropriation for maintenance for the year.	State allowance figured upon a per capita per diem basis.
Hosp. A, 20,590	$48,930	$37,500	$1.82
Hosp. B, 29,690	53,693	50,000	1.68
Hosp. C, 18,734	35,000	12,500	.66
Hosp. D, 49,629	66,162	6,875	.13

These figures relate to appropriations for maintenance; inequalities just as glaring appear among the appropriations for special purposes, as for buildings, improvements, etc.

The practice of the State of Pennsylvania in this matter is apparently far removed from any idea of justice. Planted in the soil of selfishness, the seed of favoritism produces no wholesome fruit. Such a system is bound to result in dark and vicious relations between State officials and private institutions which claim honorable recognition as philanthropic enterprises. In strong contrast to the conditions just outlined is the healthier system which, after many abortive attempts, has finally come into being in New York.

In the report on public appropriations to private charities made to the Comptroller of the City of New York in 1899 by a committee of the State Charities Aid Association, the following principles were enumerated: "(1) All institutions and societies should receive the same payment for the same class of inmates; (2) the city should make all payments to hospitals at a per capita rate instead of making an appropriation of the gross amount; (3) the city should make no appropriations for the maintenance of hospital patients, except such as are accepted as proper public charges by the Department of Public Charities after due investigation of the circumstances of such persons; and should pay for such persons only for such periods of time as are approved by the Department of Public Charities; (4) when the city maintains institutions in its own Department of Public Charities for special classes of cases, and these institutions are not filled, the city should not pay for the same class of patients elsewhere." The substance of these recommendations, as the following quotations will show, has been incorporated in the rules and regulations under which the City of New York now carries on its admirable system of cooperation with charitable institutions, and particularly with hospitals founded and maintained chiefly by voluntary contributions.

Under the rules of the Board of Estimate and Apportionment (which controls the municipal budget) all appropriations for charitable institutions are made subject to the following conditions:

"*a.* The accounts of all charitable institutions receiving public moneys must be so kept as to show receipts and disbursements in such form as shall be satisfactory to the Comptroller, showing the addresses of the parents, guardians, or nearest relatives of inmates, and other information designed to facilitate inquiry into their financial inability to provide for such inmates.

*A few of the hospitals connected with the Hospital Saturday and Sunday Association did not apply for the municipal appropriation to which they were entitled.

"*b*. All institutions receiving public moneys must be at all reasonable times open to the visitation and inspection of duly authorized representatives of the Department of Public Charities and the Department of Finance.

"*c*. Where appropriations are made upon a per capita basis, no payment shall be made for inmates of private charitable institutions unless the same shall have been accepted by the Commissioner of the Department of Public Charities as a proper charge against the city, and, except in emergency cases, the Commissioner of Charities shall not accept as proper charges against the city inmates capable of paying for their own support, or for whose care adequate provision can be made in public institutions. The city shall not become liable for any payment to a charitable institution in excess of the appropriation which may have been made to such institution, notwithstanding any per capita rates of payment that may have been fixed for the inmates thereof.

"*d*. All institutions receiving money from the city are required to state specifically the amount so received, as from the City Treasury, in their printed annual reports.

"*e*. No money may be paid to any private charitable institution which pays any salary to or gives any consideration, financial or of any kind, for services to, or that has any business dealing with, or secures goods or merchandise, directly or indirectly, from any officer or trustee or member of its Board of Managers.

"*f*. Where the city is paying 50 per cent. and upwards of the cost of maintenance of an institution, the Board of Estimate and Apportionment requires representation in the board meeting of that institution, with the right of taking part in all business transactions.

"*g*. The rates of payments to private charitable institutions, unless otherwise specially provided for, are fixed for the various classes of hospital inmates as follows:

"For infants under two years of age, and in infants' hospitals also between the ages of two and five, per day	$0.45
For maternity cases, per case	18.00
To hospitals for medical treatment, per day	.70
To hospitals for surgical treatment, per day	.90"

It must not be supposed, however, that these admirable rules have always obtained in the relations between private hospitals and the City of New York. Where all is now governed by common sense and justice, at an earlier day inequality, injustice, and unreason ruled. Only ten years ago some hospitals received per capita sums, others gross amounts, while a few hospitals received both per capita allowances and a gross amount, and the unguarded appropriations of the city were in a fair way to transfer a considerable number of hospitals from the basis of private support to that of public support. The danger of this movement to the community became so great that the report of the State Charities Aid Association, already alluded to, went so far as to declare that the plan of granting subsidies to private institutions had "inherent grave dangers which it was impossible to obviate, and that no plan could be devised which would insure wholly satisfactory results." There appears to day to be no justification for so extreme a view. Under the prevailing system in New York the private hospitals which cooperate with the city, almost without exception, obtain by their own efforts from private sources the bulk of the moneys expended by them upon plant and for maintenance, and by their continued existence and activity tend to diminish the burden of taxation for the support of the sick poor.

Wages and Welfare of Hospital Employes.—The welfare of the lower grades of hospital workers has rarely received at the hands of hospital managers such careful attention as would seem to be demanded both by the interests of the workers themselves and by the dependence of hospital efficiency on a stable and competent household organization. During the past year this subject has received special consideration from the trustees of Bellevue and Allied Hospitals and from the Commissioner of Charities of the City of New York, whose conclusions have been recorded in official reports and correspondence.

In a communication addressed to the Municipal Civil Service Commission, Commissioner Hebberd, in July, 1906, reports that hospital helpers are employed in the Department of Charities in the following numbers, at wages less than $20 per month: 36 at $5, 10 at $6, 5 at $7.50, 2 at $8, 343 at $10, 197 at $12, 250 at $12.50, 65 at $15, 11 at $16, 10 at $20.

The records of the Department of Charities show that out of 1,683 appointments in this class of workers made during a period of six months, 1,062 were dismissed for cause, 473 resigned, and only 187 were retained and promoted for good conduct. "While occasionally a fairly suitable man or woman can be had at $10 per month," writes Commissioner Hebberd, "it is impossible to manage satisfactorily the affairs of a department like this upon the supposition that any number of good employees can be had at this rate of compensation. What we are really getting to care for the sick and infirm are persons of poor character, many of them addicted to drink and others recently discharged from the workhouse. Their services are unsatisfactory and cost more in the end than would be the case if reasonable wages were paid. These cheap helpers take up not only as much dormitory space and consume as much food as good workers, but they are careless and wasteful. Having practically nothing by way of wages to lose, it is exceedingly difficult to exert any influence over these workers, particularly as so many of them are quite glad of a good excuse to get intoxicated."

Commissioner Hebberd asks for a reform in the schedule of salaries in the hospitals of his department, on the following basis: Men, first year $20, second year $25, third year (and thereafter unless promoted to a higher grade), $30; women, first year, $15, second year $20, and third year (and thereafter unless promoted to a higher grade), $25. Precisely the same schedule as that recommended by Commissioner Hebberd has been adopted by the Board of Trustees of Bellevue and Allied Hospitals, one of the three great branches of the municipal hospital service of the City of New York. This board adopted a resolution declaring that if its appropriation permitted, it would pay "a minimum of $15 per month to women employees and $20 to men, with maintenance, during the first year of service; $20 and $25 respectively during the second year of service, and $25 and $30 during the third year." In adopting this resolution the board stated its conviction that the permanent retention of an

efficient and desirable class of hospital attendants and employees is possible only on the condition of paying a wage approximately equal to that which would be given for similar service in the best private institutions.

As a further means of attracting to the service of the hospital a desirable class of workers, clubs have been organized among both the male and female employees of Bellevue Hospital, which provide social attractions and wholesome recreation for workers, some of whom if left to themselves would inevitably drift toward the street and the saloon.

Few hospitals, perhaps, without either contracting their work or finding new resources, can afford to put into effect at once the liberal wage scale to which the municipal hospitals of New York now stand committed. But while we may not have the means immediately to follow in the footsteps of these leaders in liberality, we cannot fail to commend the spirit in which the proposed reforms have been conceived, and to approve the policy which demands that if sacrifices are to be made for the support of public and private hospitals, such sacrifices must not be forced upon unwilling, low-salaried hospital workers, but should come either from the State itself, through the humane use of its resources for the support of its weaker members, or from prosperous individuals who are willing to devote a share of their surplus income to the relief of the distressed. A sense of justice demands that the wages of hospital workers be fixed on a basis consistent with their social needs, even if the total cost of hospital maintenance be thus increased.

A Chair of Hospital Management and Economics.—In closing this report I desire to call attention to the Chair of Hospital Management and Economics established in the Spring of this year by the new Brooklyn Post-Graduate Medical School. The new chair has been filled by the appointment of Dr. John J. Fitzgerald, General Medical Superintendent of the Department of Public Charities of the City of New York, who announces that instruction will be given "in methods of hospital construction, with illustrations as to detail and management; in the classification of patients, and the principles of hospital economy, etc."

Furthermore, I am in a position to announce that one of the three great universities which have medical schools in the City of New York is prepared to establish a department for the training of hospital superintendents in the principles and practice of hospital administration, and to arrange for the coordination of this department with two of the schools of the university in which cognate subjects are now taught, just as soon as means are provided for placing the new department upon a sound financial footing.

Thus approaches the realization of a hope long cherished by many of the members of this Association that the technical training of hospital superintendents might be undertaken by an educational body of dignity, learning, foresight, and influence, not for the greater glory of those who are already engaged in the labor of hospital administration, but for the greater efficiency and better social service of their successors.

Automobile Accidents.—A report issued by the Safe Roads Automobile Association shows that between June 21 and September 21 of this year forty-one persons were killed and 313 injured as the result of automobile accidents in Massachusetts, so far as they were recorded by the Association.

PSYCHIATRY AND ITS IMPORTANCE.*

By ISHAM G. HARRIS, M.D.,
POUGHKEEPSIE, N. Y.
PHYSICIAN, HUDSON RIVER STATE HOSPITAL.

Psychiatry is an important branch of general medicine, and in presenting the subject I wish to discuss the medical, the sociological, and the economical factors involved.

The defective and abnormal classes are markedly on the increase, and it behooves not only the physician but the citizen and legislator to do whatever is in the power of each to bring about an amelioration of existing conditions. In 1892 the ratio of the committed insane to the general population in New York State was 1 to 377. In 1905 this ratio had fallen to one insane in every 299 of the general population. The epileptics are, also, a numerous defective class, and the ratio is about one epileptic to every 500 of the general population. What the ratio of other defectives is to the general population I am not in a position to speak with authority.

The study of psychiatry, as a practical science, aims to determine, and to apply, the remedies best qualified to procure normal thinking and normal conduct, and, as has been said by a prominent author, "the actual cure of a case of alienation is a matter of secondary importance in comparison with the discovery of methods for preventing its spread."

There seems to be an indifference on the part of the great majority of the public concerning this important subject, and I dare say exceedingly few of our citizens are informed as to the scope and methods of the study of the most afflicted of mankind. This, however, should not be a source of much wonder when we stop to consider that it is only within the past few years that the general welfare of those suffering from mental disease has awakened the medical profession at large. It is also recently that any effort has been made to have a properly equipped hospital at the disposal of physicians for the study and treatment of disorders of the mind. In Europe a number of the large universities have connected with them specially equipped psychiatric hospitals and clinics. In this country, with one exception, no university has connected with it a psychiatric hospital.† The exception is Ann Arbor, where there has been established a psychopathic ward in connection with the Medical Department. Notwithstanding the fact that Ann Arbor is the first university in this country to establish a psychopathic hospital and clinic, the State of New York stands foremost in the line of advancement. Under the wise control of the State Commission in Lunacy some years ago, a Pathological Institute was founded in connection with the State Hospital system. It has done, and is now doing, splendid work under the direct management of Dr. Adolf Meyer. Again, the State of New York has under consideration the establishment of a psychopathic hospital in the city of New York. This hospital will not be connected directly with any university, yet it will be in a place where every possible endeavor may be made for solving problems in psychiatry, and where proper study and care may be given to all forms of alienation. Notwithstanding this, it behooves the profession at large,

*Read at the annual meeting of the Dutchess County Medical Society, January 9, 1907.

†It should be stated that Pavilion "F" of Albany, N. Y., is connected with the Albany Medical College and the course of instruction in psychiatry in this college is in connection with the Pavilion and all the medical students are given an opportunity to see and to study a number of cases of insanity.

as well as the public-spirited citizen, to insist that psychopathic hospitals and clinics be attached to our great medical universities, and that mental diseases be studied in our colleges in the same way as physiology, anatomy, general medicine, etc., are studied.

Again, each and every county in the State should have special hospitals erected for the reception of urgent and early cases of insanity. The lack of such hospitals at the present time is a great source of worry to friends and relatives in the commitment of this class to the hospitals. There is no proper place of detention. There is no place for temporary observation, and under the present system much harm is often done by delay in giving acute cases proper and early treatment. In support of this contention I have to state that in the Hudson River State Hospital, during the past fiscal year, there were admitted 525 cases, and the average duration of insanity in these cases, previous to admission, was three years. The number discharged during the year as recovered was 103, and in this number the duration of insanity, previous to admission, averaged seven months. The mere fact that these 103 recoverable cases remained without the hospital, or without proper treatment, for seven months is quite a commentary upon the way the public manifests its general indifference.

If each town or city of ten thousand or more inhabitants had a psychopathic ward or hospital many incipient cases of nervous and mental disease would receive early care and attention; also many borderland cases would come to such a hospital for advice, and thus there would be fewer wrecks to be cared for in the hospitals for the insane, and the ultimate good derived would be of great benefit to the communities and the State at large. In New York City plans are being formulated for the expenditure of between $25,000,000 and $30,000,000 for general hospitals, and so far as I have been able to ascertain not one dollar is being spent by the city for a psychopathic hospital. Just think of Greater New York, with a population of some 4,000,000 people, with all its wealth and all of its charity, and yet with no properly equipped hospital for the study and care of the most afflicted of the race! New York has a Psychopathic Ward in Bellevue and one in Kings County Hospital, but these wards are merely for temporary detention—until cases are diagnosed—then comes commitment to a hospital for the insane or discharge, as the case may demand. Albany has its Pavilion "F" for certain acute cases, and is doing good work, but aside from these places mentioned I am not aware of any other places, in this State at least, properly equipped for even temporary detention of early and suspected cases of mental disease.

The average duration of the insane life in the hospitals of this State is between ten and twelve years. It is computed by some prominent authorities that each earning individual is worth at least $150 to the State. To maintain each individual in the hospitals for the insane in this State costs about $200. The life of the insane being from ten to twelve years, it is easy to compute what an enormous expense the State must necessarily bear in properly caring for this class. The yearly cost for the committed insane, in this State, amounts to about $6,000,000. With this yearly cost and the constantly increasing number of the insane, what a problem for the sociologist!

The sociologists and the charities are doing a great deal towards the upbuilding and the uplifting of the race. Laws are being made that will tend to improve the general social and moral tone; laws as to compulsory education, laws as to child labor, laws as to hygiene and health. The question of a standard of living also claims the attention of the social worker and our reformatories are doing good work.

But what can be done from the standpoint of the sociologist that will be of use to the race from the standpoint of the student of psychopathology? We should influence the general public to arise to the necessity of the occasion by a process of education. Adapt our educational system to the demands of the child—the youth. Build up special training schools, that each child may be taught, and each may develop, along natural lines. These training schools would tend to do away with class distinction, which seems to be so prominent a feature in our present social system. We must teach health and hygiene. We must assist in raising the standard of living. We should regulate immigration by barring all defectives of whatever nature, and there should be segregation and sterilization of all incurable defectives which are so great a menace to society.

Intermarriage of defectives should be forbidden, and we should make just and utilitarian laws, the enforcement of which would redound to the good of our whole social fabric. Hysterical sentimentality should have no part in preventing the solution of a question that means so much for the ultimate good of the race.

I am quite aware that to do this requires time, a process of education and considerable money, but the general public never raises a hue and cry about the expenditures of money for educational and charitable purposes, provided it is wisely spent. The public is always ready to respond to such calls—but, gentlemen, look out for the legislator! He will howl and rage—and yet how pliable this same legislator becomes when the general public makes a demand! When the constituents speak, the legislator is as "clay in the hands of the potter."

From a medical standpoint the problems in mental disease can be solved only by assiduous study, close, critical, and painstaking observation, and satisfying results by experiments. Theoretical psychology and philosophy will not solve the problems at issue. They must be approached from various points of view: the psychological, the clinical, the physical, the chemicophysical, and the anatomicopathological. Thus we see the absolute necessity of having hospitals properly equipped for the treatment, study, and final solution of all questions involved in psychiatry.

The questions as to how to meet all the conditions connected with these problems are of great importance, and the future will have to solve many of them, but the present generation may lay the foundation upon which to build, and whatever is done must be by the cooperation of the physician with the layman; by the general education of the public.

The processes of prevention begin at home, around the family circle. It is here that the family physician can wield a mighty influence by giving proper advice to the fathers and mothers concerning the rearing and the education of the young, so that the children will not be forced into gaining knowledge along unnatural and abnormal lines. It is at the family hearthstone that the youth should be properly taught in regard to sufficient outdoor exercise, proper nourishment, and personal hygiene. Some authorities maintain that our present school system is an abnormal one and that the system is the cause of a great deal of nervous and mental trouble. On the other hand, high authorities main-

tain the adverse, that the fault is not so much in the system, which is adapted to the normal child, as it is in the fathers and mothers in desiring children who are backward to be pushed forward—to be kept up with the brighter ones.

Medically, the most important point in the study of these cases is the careful observation of symptoms and the proper analysis of such, and before we can really recognize incipient mental defect we must be able to form at least an approximate estimate of what is normal. Each and every case is one unto itself. The question involved is not whether a person is abnormal from what is considered our standpoint of the normal, but whether or not a person's normal condition has become abnormal.

When the physician is called upon to examine a patient, he has to determine if the patient is suffering from mental or physical illness, or both, and what are the demonstrable abnormalities present—he has to determine the cause of the illness, so as to form a rational course of treatment. Lastly, he has to study the case with such care and accuracy as to lead to a comprehensive knowledge of the disorder and to conclusions that are warranted by the facts obtained.

It is always extremely difficult for the hospital physician to obtain truthful records in cases of physical disorders, and such being the case you will readily appreciate how much more difficult it is to make a proper and reliable record of those afflicted with any form of mental disorder. The general practitioner has a better chance to get at many of the facts necessary for a complete understanding of the case than anyone else, and the hospital physician looks to the general practitioner for assistance, and the more observant and the more accurate one is the easier it will be to assist in the final outcome of the case. In the description of cases a confused terminology should be avoided. Simple, direct, and accurate description of what is seen and what is found should be made.

In the examination of a patient, we begin with the *family history.* Here we obtain all the information possible concerning the family, especially concerning hereditary tendencies in the ancestor, direct or collateral. If such a tendency is found we attempt to trace the probable cause, the age at which this ancestor, progenitor, or collateral was affected, and the environment in which he lived. These facts should be recorded in such a medical way as to be plain to any physician who might desire information. If no mental disorder is admitted, we should search for symptoms of mental stigmata, such as eccentricities of character, suicide, alcoholism. We should also inquire into the causes of death of any members of the family, and carefully note such causes as apoplexy, tuberculosis, heart disease, nervous affections, skin diseases, etc. The parents of the individual should receive consideration as to whether they are blood relatives; whether one or both of them are alcoholics, and whether there is any marked discrepancy in their ages. We should trace, if possible, any history of syphilis, rheumatism, bone disease, epilepsy, neuroses, etc. From family history we turn to the *personal history.*

This should include gestation, birth, infancy, and childhood. We should trace the development up to puberty, especially concerning convulsions, infectious diseases, impressionability in general, and whether the child was bright and learned readily, and whether it began to talk and walk at its proper age. The mental and physical state of the patient prior to the onset of puberty having been recorded, it is important to contrast the condition at puberty and afterward. The patient's general view of life should be taken into account, and it should be noted, if possible, "whether all the faculties developed harmoniously or whether intellectual progress took place along certain limited lines." Then we come to the *present condition* of the patient, and search for causes, stating definitely whatever may be found. All physical symptoms, the onset of the trouble, and the present illness, should be noted as clearly in detail as in a case of some infectious disease. A complete physical examination should be made and all signs of physical stigmata looked into. A minute examination must be made of the eyes, the nose, the ears, the teeth, the mouth, the gums, the secretory and excretory organs, the extremities, the genitalia, the heart, lungs, etc. Then our attention is given to the higher sensory organs and to the sensibilities. Next the cutaneous and the deep reflexes, the motor functions, the trophic disturbances of the skin, and finally the *testing of the mental state.*

The testing of the mental state will prove a most difficult problem, and will require very great patience and painstaking care, and we must remember to record only facts—clear and to the point. Arbitrary use of words should not be tolerated. In performing this duty we look for defects of judgment and intellect, for disorders of attention, of sensations, insane ideas—hallucinations, illusions, delusions, disturbances of association, of consciousness, of memory, of volition, of emotion, and of conduct.

After the mental and physical questions are thoroughly gone into we should make an examination of the sputum, blood, urine, and in many cases of the cerebrospinal fluid. Lumbar puncture, if made, should be under proper antisepsis and the spinal fluid drawn into a sterilized tube and then examined chemically and microscopically. This is often of great assistance in making a diagnosis of general paresis, of tabes, and of infectious cerebrospinal meningitis.

Until within very recent years the medical profession has been hampered by old ideas concerning the classification of mental diseases and the faults and traditions have continued to cling to us. For years and years nearly all forms of mental disease have fallen into three prominent classes: mania, melancholia, dementia, and the subdivisions of the same. Since the time of Hippocrates almost every prominent writer on mental diseases has had a classification of his own, and especially is this so since the time of Pinel, Esquirol, and Cullen. No classification, however, has been satisfactory. At the present time the majority of the leading alienists have dropped the old terminology and have placed cases with certain symptom-complexes into special groups. These groups have been given a provisional terminology merely for the sake of keeping order among facts. These groupings are based entirely upon certain fundamental traits and symptom-complexes. They are of great assistance to the medical profession and to the student of psychiatry, for whom they have certain definite meanings, and we are now better able to prognosticate and to treat the various psychoses.

Dr. Henry A. Cotton, assistant physician at the Danvers Hospital, one of the State asylums of Massachusetts, has been elected to succeed Dr. John W. Ward as medical director of the State Hospital for the Insane in Trenton, N. J. Dr. Ward recently resigned as the result of the investigation of affairs at the hospital, though it is claimed that he was not responsible for the alleged abuses reported to exist there.

RUPTURE OF THE LIVER; OPERATION; DEATH.

By H. A. HAUBOLD, M.D.,
NEW YORK.
CLINICAL PROFESSOR IN SURGERY, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO HARLEM HOSPITAL.

The importance of the location of the solution of continuity in cases of rupture of the liver, and the relationship which this bears to the probable outcome as regards the feasibility of surgical treatment, renders the case here reported of value. In a general way, it may be said that the location of the rupture usually corresponds to the site where the causative force was applied. It may also be said that, although the right lobe of the liver is the most protected portion, it is also the part most frequently ruptured. Waring of London, in his rather comprehensive work on the "Surgery of the Liver," states that Mayer reported 85 cases of rupture of the liver, in 54 of which the lesion was in the right lobe, and that Ogston reported that in 26 cases the right lobe was ruptured in 11.

The degree of force required to rupture the capsule of Glisson is considerable. This fact renders the coexistence of complicating injury to contiguous or more distant parts or organs exceedingly liable, and unless uncomplicated rupture of the gland is made the basis of an opinion as regards the mortality, conclusions from the statistics may lead to error.

My case was one of uncomplicated rupture of the liver, the lesion occurring in an exceedingly unfavorable portion of the organ as regards the application of methods of repair, and in consequence it had a fatal outcome. However, the case is submitted on the ground that no reasonable conclusion as to the utility of means of relief can be arrived at as the result of reporting only successes, and again, and more important perhaps, for the reason that the clinical picture presented by the patient was anything but classic as regards the symptoms which one had a right to expect when viewed from the viewpoint of the conditions confronting us upon celiotomy.

M. K., a Hungarian, aged 29, was admitted to Harlem Hospital on June 30, 1907, at noon. The previous morning (twenty-four hours before) he had fallen a distance of about eight feet, striking the lower portion of his right chest on the edge of a pile of lumber. The injury caused him considerable pain, but he managed to reach his home, which was quite a distance from where the injury was received, without assistance. During the night he vomited the contents of the stomach, the pain in his side became more severe, and the day following his injury he was admitted to the hospital. On admission, a linear contusion, corresponding to the area of contact with the lumber pile, was discovered extending obliquely downward and backward, beginning over the anterior portion of the seventh rib and reaching to the tenth rib about on the level with the posterior axillary line, that is, directly over the right lobe of the liver. Temperature, 99° F. in rectum; pulse, 88. The abdomen was moderately distended; no broken ribs; some rigidity, most marked over the upper segment of the right rectus abdominalis muscle. The face was pinched, but there was no pallor, nor was thirst a marked symptom. In the night the patient vomited six times. Urine was voided, but the bowels did not move.

On July 1, about fifty hours after receipt of the injury, the patient came under my observation. At this time the pulse rate was 90, temperature 99° F., the face anxious, respiration 24, abdomen moderately distended and tender, the rigidity extending over entire abdomen. This certainly was not a picture of progressive hemorrhage. Indeed, the house surgeon thought the man's condition was rather better than when admitted. However, the anxious expression of the face, the distention and rigidity of the abdomen, together with the history of the character of injury received, the presence of the contusion, as stated above, and the fact that at the end of fifty hours there was still present the evidence of some abdominal lesion led to the belief that a rupture of the liver existed and justified celiotomy. An incision through the middle of the right rectus was made, extending from the costal cartilages to opposite the umbilicus. The abdomen was full of dark fluid blood. Exploration reveaed an irregular rupture in the liver substance, situated low down in the right lobe, and so far posteriorly as to preclude repair by sewing or cautery, or indeed by any method which involved direct manipulation. The rupture was about three inches in length, and, by passing the hand down to it three fingers could be readily introduced for a considerable distance into the liver substance. There was still some oozing from the wound, but this was not so active as to cause immediate alarm. The cavity of the abdomen was freely flushed out with hot saline solution, a Mikulicz tampon was passed down to and into the wound, and slender ribbons of gauze were carefully packed into it. This seemed to control bleeding, and temporary approximation with through-and-through silkworm gut sutures was made. The patient came off the table in moderate shock; pulse, 98; respiration, 32. The tampon seemed to interfere with respiration to a considerable extent. At nine o'clock that evening the pulse had risen to 120, respiration 40, temperature 102° F.; at midnight, temperature 103° F., pulse 120. Eleven hours after the operation the patient died. At time of death the pulse was 120, respiration 45, temp. 105°.

The case presented some unique features; there was at no time any evidence of shock, nor at any time the classic picture we generally regard as indicative of progressive internal hemorrhage. Neither the rate nor the character of the pulse indicated it; the temperature was at no time subnormal, there was no thirst, no restlessness, and no air hunger. It is of course to be borne in mind that the wound in the liver substance was at a location where there are not many large blood-vessels, both the portal and arterial circulation entering farther forward, and being distributed by means of smaller branches toward the periphery, and more so is this true in respect to the particular portion of the organ involved in the trauma in this instance. What we may believe that happened is that the trauma which ruptured the liver was practically a blunt force which drove the ribs against the liver substance and ruptured it. The absence of the symptoms indicative of hemorrhage may be ascribed to the theory that the oozing was gradual and there was an accommodation of the body functions to the withdrawal of circulating fluid in this manner.

That death supervened so promptly after operative interference does not argue well for the technique employed, yet there was no other available under the circumstances. The persistent rise of temperature after the operation and up to the time of fatal outcome would argue strongly against the assumption that the bleeding had not been arrested by the measures employed. Hyperpyrexia toward the end of life is generally regarded as an exaggerated or disturbed metabolism. What connection there is between this phenomena and rupture of the liver is perhaps to be explained by the peculiar function the liver has as an internal secreting organ.

15 WEST EIGHTY-EIGHTH STREET.

The Pathology of General Paralysis of the Insane.—W. Ford Robertson declares that the etiology and pathogenesis of this disease have hitherto remained a profound mystery. There has recently been noted a growing dissatisfaction with the syphilitic hypothesis. There exist many weighty arguments against the view that general paralysis and tabes dorsalis are essentially syphilitic in their origin. There is unquestionable evidence that the general paralytic suffers from an active bacterial toxemia. Syphilis doubtless plays an important part, but it is merely that of weakening the general and local defences against bacteria. The writer then describes in some detail investigations which he offers as evidence that a diphtheroid bacillus, either an attenuated form of the Klebs-Löffler bacillus, or more probably an altogether distinct microorganism, is the specific etiological factor in general paralysis and tabes dorsalis. According to Orr and Rows tabetic lesions of the cord can be produced by the absorption of toxins from peripheral septic foci. The writer concludes by saying that the general paralytic defends himself and often with success for some time by manufacturing specific bacteriolytic antibodies. He believes it worth while to produce such antibodies in suitable lower animals in order that they may be used as therapeutic agents.—*The Scottish Medical and Surgical Journal.*

Enuresis: With Special Reference to Its Etiology and Treatment.—James Burnet does not regard bedwetting as pathological until the period of infancy has been passed. Every case of this kind that is brought to a physician for treatment should be most carefully investigated, as no permanent result can be expected from remedies unless the ultimate cause has been accurately determined. The writer believes that enuresis is most frequent in nervous children, many of whom are of a rheumatic heredity, and that in a few patients other causes, local it may be, or general, contribute to its onset. He does not think that adenoids, phimosis, or oxyurides conduce to its onset. However, he is strongly of the opinion that constipation is a potent factor. If, after the examination has been made, and no local exciting agent, nor any rectal or urinary abnormality apart from constipation and hyperacidity of the urine be found, a thorough evacuation of the bowels should be obtained by the administration of calomel, castor oil, or preferably by means of a large olive-oil enema. The foot of the bed should be raised, and the patient should rest on one side, and not upon his back. The elimination of starchy food from the diet is helpful in some cases. A diet consisting largely of eggs, milk, fish, and fruit is advantageous in these cases. Nothing should be given the child to drink two hours before retiring. The patient should empty both the bowels and bladder just before going to bed. Drug treatment the writer considers secondary to the more general treatment. Strychnine with tincture of belladonna may be given. A spinal douche night and morning with cold water, followed by rough towelling of the skin is advisable. Treatment of the disturbance of the bladder or any other condition giving rise to this affection may be necessary.—*Treatment.*

The Treatment of Uric Acid.—James F. Goodhart declares that to him the presence of uric acid in the urine seems to be an absolute puzzle. He insists that "acidity" is brought about in several ways; at least it does not attach itself exclusively to any one class of food. If, however, any one should be banned on this account he would suggest the carbohydrate group and not the flesh group. In many, perhaps in most cases, diet is not the initial fault. He cannot detect the predominant evil influence of meat in causing the appearance of uric acid in the urine. He argues against the rich or mixed living which is so common. He thinks that perhaps rich gravies, sauces, spices, and pepper may have an adverse influence. He believes that those who are inclined to the passage of uric acid should be careful as to the consumption of unadulterated starch, and sugar, and fat, including cream. He thinks also that these articles of diet are probably digested more easily earlier in the day than later. Salt is another article of diet not above suspicion. Of some of the acid fruits he thinks the same. Vinegar is indigestible either in itself or in its influence on other foods if taken in any thing more than a mere flavoring quantity. Wine also is more prone than food to call out erratic tendencies on the part of the digestive processes. In a large number of cases the formation of uric acid is first of all a nervous aberration by which all the natural digestive processes are upset, uric acid being the result of the imperfect combustion. Such patients should observe strict moderation in all things apart from tonics, cures at watering places, and change of scene and air, the use of half a dram of bicarbonate of potash in a tumbler of water at bedtime is one of the most useful remedies.—*The Practitioner.*

Transmissibility and Curability of Cancer.—William Seaman Bainbridge, after reviewing the evidence concerning the theories of heredity, congenital transmission, and infectiousness or contagiousness as causal factors in the production of cancer, concludes that heredity and the congenital transmission of cancer are subjects which require much more study before any definite conclusions can be formulated concerning them; that the contagiousness or infectiousness is far from proved; that evidence in support of the theory is so incomplete and inconclusive that the public need not be alarmed concerning it; that the danger of the accidental acquirement of cancer is far less than that of typhoid fever, syphilis, or tuberculosis; that in the case of cancer there is much more danger to the attendant of septic infection, of blood poisoning from pus organisms, than from any possible acquirement of cancer; that the communication of cancer from man to man is so rare, if it really occurs at all, that it can practically be disregarded; that in cancer, as in all other disease, attention to diet, exercise, and proper hygienic surroundings is of the utmost importance; that cancer is local in its beginning; that, when accessible, it may, in its incipiency, be removed by radical operation so perfectly that the chances are overwhelmingly in favor of its nonrecurrence; that once it has advanced beyond the stage of cure, in many cases suffering may be palliated and life prolonged by surgical means; that while other methods of treatment may, in some cases, offer hope for the cancer victim, the evidence is conclusive that surgery, for operable cases, affords the surest means of cure.—*Boston Medical and Surgical Journal.*

The Thymus and Death in the Course of General Anesthesia.—André Lapointe ranks among the conditions that render anesthesia dangerous abnormal persistence of the thymus gland after birth. It is associated with hypertrophy of the lymphatic organs and the lymphadenoid tissues. The author has found in literature 33 examples of sudden death under general anesthesia in such persons, and to them adds two observed by himself. The dominant symptom is the presence of a large thymus. The evolution of this gland consists of a period of growth, followed by one of regression ending normally in the second year of life, abnormally from the fifth to the twenty-fifth year. There are vestiges of the gland even in the most advanced age. Histological changes go on that are curious; at first they are epithelial, later fatty changes go on. Persistent thymus is only one feature of the *status lymphaticus*. There is almost always enlargement of the lymphatic glands, and exuberant adenoid tissue in the pharynx, and in the Peyer's patches of the intestine. Sometimes the thyroid is also hyperplastic, and there is corpulence combined with the other changes. The form of anesthetic used seems to have no effect on the occurrence of sudden death in such subjects. The respiration becomes slowed, and the pulse imperceptible; then the heart stops and the pupils dilate rapidly. Artificial respiration will cause a few breaths after the stoppage of the heart. The theory of compression of the trachea and great vessels by the thymus is hardly tenable as a cause of death. No compression has been found at the autopsy in any case. Hyperthymization, that is that the thymus throws into the circulation toxic substances that create a pathological excitation of the cardiac nervous centers, which react reflexly, is also proposed. On this supposition it is advisable to lessen all nervous excitations before the operation by the use of drugs. In every case in which there are evidences of the *status lymphaticus*, scopolamine-morphine solution should be injected so as to produce a calm sleep, and then anesthesia should be begun during the sleep.—*Le Progrès Médical.*

Asymmetrical Pelves in Obstetrical Practice.—Fieux describes asymmetrical pelves as true oblique-oval pelves, Naegele's pelvis, and pseudo-oblique-oval pelves. The first are rare, and due to lack of development of one wing of the sacrum and iliac bone, from ankylosis of the synchondrosis. Commoner are those due to lack of development of one side of the pelvis due to some lesion of one limb producing limping. Scoliosis combined with lateral curvature may also cause it. The anteroposterior dimensions are normal provided rickets is not combined with it. The diagnosis is easier in Naegele's pelvis, since it may be seen by external examination, while in the other form it is only discovered by vaginal examination under chloroform. In Naegele's pelvis one hip and one buttock are overdeveloped and the others are flattened. In the pseudo-oblique-oval form under chloroform the hand reaches the innominate line on the deformed side and finds it horizontal and pointing to the body of the first sacral vertebra. In the less marked deformities natural deliveries are possible, while in severe forms interference is necessary. The forceps is of little use; version is better; symphyseotomy or cesarean section are often needed.—*Journal de Médecine de Bordeaux.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, October 26, 1907.

BLOOD CULTURES IN TYPHOID FEVER.

THE truth that typhoid fever is a preventable disease has been well impressed upon the present generation of physicians. It is certainly true that a pure milk and water supply, proper sewer construction, and other sanitary measures, will spare any community the frightful epidemics of a few years ago with the enormous economic losses accompanying the unnecessary sacrifice of human life and health. But the physicians of a community, in their more limited sphere of action, can independently contribute very much to the disappearance of this scourge by such handling of all suspicious, as well as frank cases of typhoid fever as will give the least opportunity for the spread of the disease from such individual foci of infection. The possibilities of such work are shown by the brilliant record of Robert Koch in Trier, where the isolation and cure of some seventy cases of the disease existing on his arrival rendered the community typhoid-free for the time being. The proper treatment of all excreta, the instruction of the attending nurses and relatives in their conduct, the administration of urinary antiseptics to convalescents, are all methods toward such end, but perhaps the most important of all is the diagnosis of each new case at the earliest possible moment. Only with such diagnosis the proper precautions may be instituted and their importance impressed upon those surrounding the patient.

In this connection the use of the Widal agglutination reaction has led to a great advance over the methods of the purely clinical era that preceded the present laboratory and bacteriological methods of diagnosis; of late the custom of making routine blood cultures in all suspicious cases has brought us nearer to the prompt and sure diagnosis of the disease, positive results having been obtained in from 70 per cent. to 100 per cent. of the cases examined. The present desideratum, however, is such simplification of this valuable method as will enable the attending physician to do the work in his laboratory, though lacking the facilities of a well-appointed hospital. In No. 27, Vol. VI, of *Russkii Vratch*, Dr. Padlevsky describes his experience with one such method, namely, the use of bile recommended by Conradi and Kayser to enrich the culture medium. The bile was obtained fresh from the slaughter-houses and then sterilized by steam for half an hour on three successive days. About 1 c.c. of blood obtained from the veins of the arm was mixed with twice the amount of bile and then incubated for from 16 to 24 hours. The mixtures were then examined in smears and hanging drops and transfers were made to agar and other media. The growth on these appeared some five or six hours later, and therefore a diagnosis could be made in from 30 to 32 hours after the blood was first taken. In 119 cases examined positive results were obtained in the first week of the disease in 92.3 per cent., during the second week in 72.4 per cent., during the third week in 66.6 per cent., and in 33.3 per cent. in the fourth week.

Of greater interest is the more extensive and original work of Dr. Klodnitzky appearing in the same and successive numbers of *Vratch* (Nos. 27, 28, 29, Vol. VI). His method of bacteriological examination of the blood is founded upon the claim that it is not the enriching of the media by such elements as bile, peptone, etc., that leads to the growth of the bacteria, but the destruction of the red blood corpuscles accompanying the laking of the blood and the abolition of such bactericidal properties as these formed elements of the blood may possess. Accordingly, he simply mixed the blood with sterile water, using this as the first medium because of the hemolysis thus produced. Cultures were obtained in 73 per cent. of the one hundred cases of typhoid fever examined; as the work was done in the Kharbin laboratory during the recent Russo-Japanese war, and was hampered by all the difficulties attending an experimental laboratory in time and place of war, these results compare very favorably with those obtained by other methods. They are important, moreover, by supporting the theory of the bactericidal influence of the erythrocytes or their products, which may have a wider application than the blood culture work alone.

These two papers show the direction in which bacteriologists are at present working in simplifying the positive diagnosis of typhoid fever at the earliest moment possible, facilitating thus the treatment of the disease and the prevention of epidemics. With further progress it may be hoped that bacteriological examination of the blood in suitable cases may enter as much within the province of a practitioner as the search for malarial organisms in the blood of patients suffering from intermittent fever.

WHAT HEALTH DEPARTMENTS CAN DO TO SECURE PURE MILK.

THIS was the title of an extremely interesting paper read last week at the meeting in Buffalo of the health officers of the State by Dr. Thomas Darlington, Health Commissioner of New York City. The paper not only was interesting in its account of the praiseworthy efforts of the Health Department to safeguard the consumers of milk in this city, but also presented an unanswerable argument for the municipal pasteurization of the bulk of the city's milk supply. "The problem of a pure milk supply for a city is solved," Dr. Darlington said, "when the Department of Health can guarantee that all milk sold within the city limits is drawn from perfectly healthy and normal cows, housed in comfortable and sanitary quarters, milked by a clean and healthy person into a sterile container, quickly cooled, transported, and delivered to the consumer in a sealed package." So far we are in perfect accord with the Health Commissioner, and when such perfection is reached we shall advocate the destruction or the storage of

all pasteurizing apparatus. How far we are at present from such perfection, Dr. Darlington was at haste to demonstrate.

The daily milk supply of New York, he said, amounts to 1,750,000 quarts, gathered from over 35,000 farms, and shipped from about 700 creameries located in six States. The supervision of these 35,000 farms is entrusted to sixteen inspectors, or one to something over 2,000 farms. Each of these officers inspects on an average ten farms a day, which, allowing for time in traveling between the different farms, would give him perhaps thirty minutes for each farm. If even such brief visit could be made every week, or every month, there would be some ground for confidence that the rules of the Health Department were strictly followed, and that the river of milk flowing into the city was reasonably pure. But each farm is visited, not every week nor every month, but only once a year. For three hundred and sixty-four days out of the three hundred and sixty-five the farmer is secure from prying eyes and an inquisitive nose, and can amuse himself, after morning prayers, with a reading of the Department's dairy rules, printed on linen and hanging on the wall of his milk shed. The faith that would accept such inspection as a guarantee of purity in the milk supply would move Mount Everett to Central Park.

The efforts of the Health Commissioner to secure a pure milk supply for this city are deserving of all praise, and we have no will to belittle them. He has accomplished wonders with the small force of inspectors at his command, and the refusal of the Board of Estimate to give him the money to increase this force is shortsighted and deplorable. Nevertheless, with as many inspectors as the most liberal and hygienically farseeing Board could possibly allow him, competent supervision of these 35,000 farms will be impossible. An army of five hundred men at least would be needed to make the inspection efficient, and even if so many intelligent and competent men could be found for the work, the expense would be such as no Board of Estimate would or could ever sanction. The most that can be hoped for from the most thorough inspection possible is that the milk supplied to the city shall be macroscopically clean—free, that is, from admixture of manure and other gross impurities—and containing only a few thousands of the ubiquitous bacteria to the cubic centimeter. Even then there could be no certainty that the milk would be always absolutely sterile as regards the bacilli of tuberculosis, typhoid fever, and diphtheria, to say nothing of occasional accidental contamination with other pathogenic germs. With the best inspection possible under existing, or any practically conceivable conditions, the great bulk of milk delivered in New York every morning will only be fit for pasteurization—and even that is as yet far from realization. Nevertheless, our present milk supply can be rendered reasonably safe by pasteurization, which kills the existing germs even if it does not destroy the toxins already formed or prevent subsequent growth when not kept cool and in sealed receptacles. The only safety for the consumers of milk in this and other cities throughout the country lies in municipal pasteurization, conducted under constant supervision of the Health Department, of all except an insignificant fraction of the milk supply. Even that fraction would be made safer by heating for twenty minutes to 155° Fahrenheit and subsequent cooling of the sealed bottles containing it to 40°. In pasteurization only, supplemented by conscientious and thorough inspection, will be found a solution of the problem of a pure milk supply.

PRIMARY TYPHLITIS.

THERE is considerable diversity of opinion as to whether inflammation of the cecum occurs independently of similar involvement of the vermiform appendix, some denying the occurrence of such a condition, while the majority at least admit its possibility. The weight of evidence further seems to support the latter position. The recognition of this fact is of prime importance, as ablation of the appendix may fail to relieve the symptoms in a given case, while omission to take account of the lesions in the cecum may result in unanticipated disaster. In illustration of this statement, Dr. G. A. McWilliams, writing in the *Annals of Surgery* for June, reports the case of a man, 48 years old, who presented symptoms of acute appendicitis, with encapsulated abscess. At operation the appendix was found practically normal, while the cecum was enlarged, thickened, and congested. Accordingly, this portion of the bowel was resected and anastomosis established between the ileum and the colon. Although the patient reacted well from the operation, he died on the following day as a result of acute dilatation of the heart. Post-mortem examination disclosed a condition of primary acute suppurative inflammation of the cecum, with secondary inflammation of the appendix.

From the conditions present in the case reported, in conjunction with a study of the literature of the subject, the conclusion is reached that primary acute and chronic typhlitis does occur independently of appendicitis, dysentery, tuberculosis, actinomycosis, or carcinoma, and may be idiopathic in origin or depend upon coprostasis. The condition may, in the presence of a normal appendix, lead to perforation, with the formation of perityphlitic abscess or general peritonitis. The symptoms of primary typhlitis are usually identical with those of appendicitis, and the indications for operation are similar in the two conditions. Primary typhlitis is rare in comparison with the frequency of appendicitis. The differential diagnosis of inflammatory typhlitis from tuberculosis, carcinoma, and actinomycosis may be impossible at operation, and in such an event a section of the cecum should be removed for microscopical examination. The recurrence of symptoms after removal of the appendix may be due to attacks of typhlitis, and the treatment for this condition consists in regulation of the diet and the employment of oil enemata, etc. The danger from primary typhlitis consists in the liability to rupture of an ulcer and to the development of appendicitis. Purgatives are held to be contraindicated in the presence of inflammation of structures in the right iliac fossa, because of the danger of superinducing rupture of an ulcer in the cecum or appendix, or of breaking up adhesions about an abscess. The treatment of primary typhlitis consists in abdominal section, removal of the appendix, closure of any perforation if possible, invagination of any threatening perfora-

tion of the cecum, drainage of the right iliac fossa, and the removal of a section of the wall of the cecum for microscopical examination for purposes of diagnosis.

A CURE FOR EXPERIMENTAL NAGANA.

From the time that European nations began to colonize Africa, it was found that their colonies could develop only when certain diseases, which killed many persons each year, could be cured or prevented. Investigators soon found that trypanosomes were not, as first supposed, harmless parasites found in the blood of rats, but were the cause of several animal diseases as well as of sleeping sickness. Like the malaria parasites, these are transmitted by the bites of insects which have sucked the blood of infected individuals or animals. Since a specific remedy for malaria existed, reasoning from analogy, suggested that there should also be one for the trypanosomes. Up to the present time preparations of arsenic have been the only ones which have given any satisfactory results. Sodium arsenate gave doubtful results, its injection causing abscesses and ulcers. Atoxyl was tried, and, while not causing abscesses and giving some good results in sleeping sickness, was not found altogether satisfactory. Ehrlich and Shiga tried trypan-red, parafuchsin, and malachite-green, none with perfect results. In short, all the remedies cured but few animals and produced only a temporary effect in others, often inducing a fatal poisoning instead of a cure.

Loeffler and Rühs instituted a series of experiments in the laboratories at Greifswald (*Deutsche medizinische Wochenschrift*, August 22, 1907) on rabbits, guinea-pigs, and rats with nagana trypanosomes of marked virulence, the latter killing an untreated animal in five to six days. Atoxyl and trypan-red were tried separately and combined, with no better results than other observers had obtained in other trypanosome diseases. They then tried sodium arsenate intraperitoneally, as it caused abscesses when given subcutaneously. They found that the preparation varied in strength, and hence only used that prepared according to the Ziemssen method; this cured some animals, while others were not cured, and still others died of arsenic poisoning. The sodium arsenate was then tried in combination with atoxyl with good effect upon the trypanosomes, although many more animals died of arsenic poisoning than when the sodium arsenate was used alone. Atoxyl being neutral, they attributed this more deadly action to the diminished alkalinity of the mixture. They then first neutralized the sodium arsenate with acids before mixing it with atoxyl when they found the effect of the mixture still more poisonous, but still effective as regards the trypanosomes; when the mixture was made acid the effect was again more marked, nearly all the animals dying on whom the treatment was tried. From these experiments they concluded that arsenous acid was the active drug in the mixture, and this was now tried alone. A one tenth per cent. solution was prepared, of which 0.012 to 0.018 gram for each kilo of weight would kill a guinea-pig when given by mouth, 0.004 to 0.006 gram being enough to cause the trypanosomes to disappear from the blood for five days. When this dose was given five times, at five-day intervals, all infected animals were cured and healthy animals did not develop the disease when injected with trypanosomes, provided the arsenous acid treatment was carried out first. All animals were cured, and none died of arsenic poisoning, while in reality less arsenic was injected than when the other preparations were used. They usually began with a smaller dose when the animals were very sick. Loeffler and Rühs believe that as this remedy cures and acts as a prophylactic in nagana it might also be of avail in the other trypanosome diseases.

LOW-FREQUENCY ALTERNATING CURRENTS IN THE TREATMENT OF ATONY OR DEGENERATION OF MUSCULAR TISSUE.

It is not many years since the electrical treatment of certain diseases, generally of nervous origin, was initiated. D'Arsonval is perhaps still the greatest authority on the subject, and his works remain text-books. At first, in fact, up to quite a recent date, high-frequency currents were the vogue, and currents of prodigious rapidity were employed. Of course, high frequency currents are still widely used, but there now seems to be an increasing tendency on the part of those who practise electrotherapeutics to rely more than formerly upon low-frequency currents for the relief of certain well-defined disorders of the nervous system.

Dr. Reginald Morton, who is medical officer in charge of the electrical department of the London Hospital, at which hospital is the largest installation of light and electric appliances for the treatment of disease of any institution in Great Britain, read at the recent meeting of the British Medical Association a paper dealing with the efficacy of low-frequency alternating currents. He said that a current slowly undulating and periodically reversing its direction had always appealed to him as a therapeutic agent possessing great possibilities. High-frequency currents with their thousands and tens of thousands of reversals per second, were at one end of the scale, and low-frequency currents, with one to four or six reversals per second, were at the other end of the scale. He thought that high-frequency currents were finding their level, and if the electrical reactions of muscles so affected were tested, it would be usually found that there is a prolonged latent period, a prolonged period of contraction, and it might also be found that there was a prolonged period of relaxation. It must also be borne in mind that there is normally a longer latent period and a longer period of contraction in unstriped involuntary muscle than is found in healthy voluntary muscular tissue.

It has seemed to Dr. Morton, in treating such cases, that to get the best results something more stimulating should be employed than the constant current, but if it was decided to use a variable or undulating current, one should be selected in which the successive waves should not follow one another too rapidly. The low-frequency sinusoidal current possessed all the advantages of the constant current and few of its disadvantages.

At the London Hospital are arrangements by which a constant current, a sinusoidal current of

about 15 cycles per second, and another of about 1 or 2 cycles per second, are instantly, and at all times available, and Dr. Morton's experience has been that the sinusoidal currents are more and more used with good results. Certain cases greatly benefited by the application of these currents are those of an atonic condition of unstriped muscle, among which may be included the atonic dyspepsias and constipation due to atony of the colon.

THE EPIDEMIC OF INFANTILE PARALYSIS.

Many communities, among them the city of New York, are suffering this autumn from a rather severe epidemic of anterior poliomyelitis. As usual, the great majority of sufferers are children, yet in the present visitation not a few young adults have been attacked. The disease has ever been a mystery as regards its etiology, from the time it was first recognized as a pathological entity by Duchenne. Many of its features would stamp it as an acute infectious disease, but its microbial cause, if such exists, remains to be discovered. It is at times such as this, when the disease is rife and physicians, warned by its prevalence, are in position to make an early diagnosis, or at least to suspect its presence, that the opportunity is at hand to solve the mystery of its causation.

Physicians, especially those whose practice is mainly among the poor—though the present epidemic is by no means confined to this class—should be suspicious of every case of undefined pyrexial disease in a child, and should subject it to a thorough bacteriological examination. We are informed that the directors of the Rockefeller Institute and of the Research Laboratory of the Department of Health, if requested by the attending physician, will gladly undertake to have lumbar puncture performed and a bacteriological examination made of the cerebrospinal fluid. This will be done without expense to the patient's family or medical attendant. Doubtless the same will be done by the neurologists and bacteriologists connected with other research laboratories in this and other cities.

We would call attention also to the collective investigation undertaken by the New York Neurological Society and the Pediatric Section of the New York Academy of Medicine, announcement of which is made elsewhere in this issue of the Medical Record. In order to make this investigation of value, the cordial cooperation of the practising physicians of the city is essential. Although the epidemic is apparently on the wane, there is still time for the collection of much valuable information and of data affording matter for productive study.

If as many fresh cases could be seen and studied every week as there are old cases brought in the same period of time to the orthopedic institutions of the city for treatment of the resulting paralytic deformities, a long step would be taken toward a solution of the etiological riddle of infantile paralysis.

Uncontrollable Vomiting of Pregnancy.

It is rather curious that it is only within the last fifty years or so that this affection has received much attention from obstetricians; at least the writings of the earlier authorities, who certainly were not deficient in powers of observation, contain but few and brief references to this complication. Apparently it is becoming more prevalent unless, as Freund suggests in the *Deutsche medizinische Wochenschrift*, October 3, 1907, the diagnosis is made more frequently than in former generations, because the limits of "uncontrollable" are much more widely set than was formerly the case. Freund, although he attaches due weight to the various theories of intoxication and reflex causation that have been advanced, and even points out a new source of the latter, viz., congestive conditions in the nasopharynx, is inclined to lay much stress on the psychical factor, which he regards as of great significance. The nervous form of so-called uncontrollable vomiting, he says, is the most frequent, and this in most cases is curable through psychical and dietetic treatment. This is to be carried out by a more or less protracted period of rectal feeding, during which nothing is taken by mouth, while the patient is isolated from family and friends, and is cared for only by attentive, but not unduly sympathetic strangers. In some cases the purely psychical nature of the affection has been demonstrated by the prompt relief afforded by a fictitious operation supposed by the patient to be an abortion, and which was not followed by a relapse when the truth became apparent. For the few cases in which abortion must actually be resorted to as a last resort, he recommends performing the operation at one sitting, and as quickly as possible. He urges greater efforts at prophylaxis, however, early in the pregnancy by the careful search for, and removal of, all possible sources of reflex irritation, and especially by a suitable psychical régime, in which of course the personality of the physician is of paramount importance.

The Influence of Diet in Tuberculosis.

Although the importance ascribed to the management of the diet in tuberculosis is justified both by practice and theory, there is still a great deal to be learned in regard to the actual manner in which modifications of the character of the food influence metabolism in general and the resistance to disease in particular. An interesting contribution to this aspect of the science of dietetics is furnished by Weigert (*Berliner klinische Wochenschrift*, September 23, 1907), who fed dogs and guinea-pigs on diets of different kinds, and then analyzed the bodies of the animals. In this way he was able to determine that the chemical composition of the animal body is susceptible of modification by variations in diet, and especially that the percentage of water fluctuates according to the type of feeding. Young animals and those receiving a preponderatingly carbohydrate diet exhibit the greatest water content, while animals fed largely on fatty food manifest an increase both in nitrogen and mineral ash. One series of the author's experiments was devoted to investigating the dietary conditions in tuberculosis. For this purpose two sets of young pigs were fed for some time on fatty and carbohydrate foods respectively, and were then inoculated with perlsucht bacilli. The results were strongly in favor of the fatty regimen, for the animals that had received only food of this description were at autopsy found in better general condition and with less extensive tuberculous lesions than the members of the other group that had been nourished on sugars and starches. This result is in accord with clinical experience, and the author's conclusion that an insufficiency of fatty foods among the poorer population is a contributing factor in the spread of tuberculosis, is only a confirmation of what has long been recognized empirically.

News of the Week.

Collective Investigation of the Poliomyelitis Epidemic.—A committee has been appointed by the New York Neurological Society to cooperate with a committee appointed by the Section on Pediatrics of the New York Academy of Medicine in a collective investigation of the present epidemic of anterior poliomyelitis. The members of these committees are anxious to make a thorough investigation of, and to collect all the data relative to, the epidemic of poliomyelitis of 1907 in New York City and its immediate vicinity. To this end they must have the cooperation of all those who have had, or will have, an opportunity of studying this disease in hospital or private practice. Physicians willing to assist in this work will kindly inform the Secretary, Dr. Edwin G. Zabriskie, 37 West Fifty-fourth Street, New York City, who will send them history forms so as to secure uniform records. Physicians who cannot collaborate with the committee will confer a favor by reporting to the Secretary the number of cases of poliomyelitis they have treated during the past six months. The joint committee wishes to state most emphatically that due credit will be given to everyone who contributes to this collective investigation, and that the publication of the committee's report will in no wise interfere with any article or articles to be published on this subject. Moreover, the committee's report will surely not be printed earlier than a year from date, so that medical men will have ample time to publish their articles long before the committee will have its report ready. Signed: B. Sachs (Chairman), E. G. Zabriskie (Secretary), J. R. Hunt, J. F. Terriberry, L. Pierce Clark, of the Committee of the Neurological Society; L. E. La Fétra, Herman Schwarz, L. C. Ager (Brooklyn), of the Committee of the Section on Pediatrics of the New York Academy of Medicine; Simon Flexner, for the Rockefeller Institute; C. F. Bolduan, for the Department of Health, New York City.

Harvey Society Lecture.—The first lecture in the present course will be delivered by Professor E. O. Jordan of Chicago University on Saturday evening, October 26, at 8:30 P.M. Subject, "The Problems of Sanitation."

The Herter Lectures at the Johns Hopkins University.—These lectures will be given at the end of April, 1908, by Professor Edward A. Schäfer, who holds the chair of physiology in the University of Edinburgh.

The Hospital Conference of the City of New York will hold a meeting to which the public is invited at the Academy of Medicine on Wednesday evening, October 30, 1907. Dr. W. Gilman Thompson will deliver an illustrated lecture on "Modern European Hospital Construction."

Measles in a Pennsylvania City.—It was discovered last week that a large proportion of the children attending the public schools of Allegheny were suffering from measles. In one school alone two hundred and fifty cases of the disease were found, and the school was closed. The Superintendent of the Board of Health has issued a warning to parents announcing that he would prosecute all persons found sending their children to school when they knew that they were suffering from measles.

Plague in San Francisco.—Plague is decreasing in San Francisco, and no additional cases have been reported since the middle of the month. There have been seventy verified cases, with forty-three deaths, thirty-two suspects are under observation, seventeen patients have been discharged as cured, and ten patients are under treatment.

Cholera in Russia.—Although the disease continues to advance and new provinces are being officially included in the danger zone, the authorities are feeling more hopeful, as they attribute the spread of the disease to the exceptionally mild autumn weather, and expect the epidemic will be checked with the advent of winter.

To Examine the Eyes and Ears of School Children.—The State Department of Health has sent to each of the 446 incorporated villages in the State a complete set of forms with instructions for the examination of the eyes and ears of school children in the public schools of those villages. It is proposed to have the teachers carry out the examinations under the cooperation of the local health officers, though it must be admitted that the value of statistics obtained in this way will be open to serious criticism.

To Bar American Canned Goods.—The Mexican national Board of Health contemplates issuing an order prohibiting the sale of imported canned goods in Mexico. An official investigation has resulted in the charge that American manufacturers and dealers in these goods have used Mexico as a dumping ground for adulterated and impure stock since the pure food law went into effect. It is alleged that much sickness has lately been caused in Mexico from the consumption of imported canned goods.

Milk Dealers Fined.—Thirty retail milk dealers were fined from $10 to $50 each in the Court of Special Sessions last week for selling adulterated milk. Thirteen wholesale milk dealers were also arraigned on charges of having unclean cans, but the court held that the retailers should have cleaned them before sending them back, and the wholesalers were all discharged.

Pasteurized Milk Plants in the United Kingdom.—Mr. Nathan Straus of this city has offered to present the cities of Dublin and Liverpool with pasteurizing plants for the preparation of milk to be used in infant feeding.

Admission of Homeopathic Graduates.—At a largely attended business meeting of the Philadelphia County Medical Society held October 16 an amendment to the by-laws was adopted making eligible for membership any reputable graduate of not less than a year's standing from a medical school legally authorized to confer the degree of doctor of medicine, who has complied with the requirements of the medical examination laws, and who abjures all sectarian designations.

Entertainment of German Scientists.—It is reported that the citizens of Dresden and the public press have objected to the money spent by the municipality in providing for the entertainment of those attending the seventy-eighth Congress of German Men of Science and Physicians held in Dresden last month, and have severely criticised the practice of public entertainment on such occasions. The city of Dresden appropriated for the purposes of the Congress the sum of 20,000 marks, of which 14,000 marks was spent for entertainment.

Liverpool School of Tropical Medicine.—The Liverpool School of Tropical Medicine has received from the British Government an additional grant of $2,500 a year, increasing the resources of the institution to $5,000 a year for five years.

Bequests to Boston Institutions.—Among the charitable bequests made by the will of the late Miss

Florence Lyman of Boston, the Carney Hospital of Boston is to receive $30,000 and the St. Mary's Infant Asylum $25,000. The Carney Hospital is also to receive a share of the residuary estate.

Gifts to a Philadelphia Hospital.—A gift of $10,000 has been awarded by the executors of the Dulles estate to the Woman's Hospital of Philadelphia for the building of a children's ward in memory of Mary Cheves Dulles. The hospital has also received the sum of $5,000 from the estate of Miss Rebecca White, in whose memory the managers will endow a bed.

Two New City Hospitals.—Contracts for two new hospitals have been awarded by the Commissioner of Charities. One of them will be on Staten Island and the other at Coney Island. The former will consist of eight buildings, for which an appropriation of $2,000,000 has been made. The institution will be known as the Sea View Hospital, and is to be at Spring Valley, Manor Road, Staten Island. When completed the hospital will accommodate 800 patients. The pavilions will be four stories in height and of reinforced concrete. The new Coney Island hospital will be located on Ocean Parkway, and will cost $328,475. This building will be four stories in height and of reinforced concrete. It will be used for acute and general medical cases.

Henrotin Memorial Hospital of Chicago.—This institution will be opened on or about November 1. It is a six-story structure of reinforced concrete, with sixty rooms for patients, the result of long planning by the late Dr. Fernand Henrotin. The president of the Association (Polyclinic Hospital Association), Dr. John H. Chew, states that the prices will be similar to those of other hospitals, and that the institution will be open to the patients of all reputable physicians.

The Dunning Institutions will probably soon be turned over by Cook County to the State of Illinois for an insane hospital. The county will have a new poor farm and infirmary, and its Dunning Hospital for the Insane will be given over to State control. These prospective changes are the outgrowth of an exhaustive inquiry made into the conditions existing at the Dunning poorhouse.

Dr. Henry A. Cotton, assistant physician at the Danvers Hospital, one of the State asylums of Massachusetts, has been appointed to succeed Dr. John W. Ward as medical director of the State Hospital for the Insane in Trenton, N. J.

Dr. William L. Estes of South Bethlehem, Pa., surgeon to St. Luke's Hospital, celebrated on October 18, with appropriate ceremonies, the twenty-fifth anniversary of his connection with the hospital.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the Alvarenga Prize for 1907 has been awarded to Dr. William Louis Chapman, Providence, R. I., for his essay, entitled "Post-operative Phlebitis, Thrombosis, and Embolism." The next award of the prize, amounting to about $180, will be made on July 14, 1908. Particulars may be obtained from Dr. Thomas R. Neilson, secretary of the College of Physicians of Philadelphia.

Meriden (Conn.) Medical Society.—The following officers were elected at the annual meeting of this society held on October 10: *President,* Dr. E. W. Smith; *Vice-President,* Dr. H. A. Meeks; *Secretary and Treasurer,* Dr. H. D. Lockwood.

Wright County (Minn.) Medical Association.—At the annual meeting of this organization held in Buffalo on October 12, officers were elected as follows: *President,* Dr. A. M. Ridgeway of Annandale; *Vice-President,* Dr. C. L. Larsen of Buffalo; *Secretary,* Dr. John T. Catlin of Buffalo; *Treasurer,* Dr. A. L. Hill of Monticello.

Vermont State Medical Society.—Officers were elected as follows at the ninety-fourth annual meeting of this organization held in St. Johnsbury on October 11: *President,* Dr. G. H. Gorham of Bellows Falls; *Vice-President,* Dr. J. F. Blanchard of Newport; *Secretary,* Dr. C. H. Beecher of Burlington; *Treasurer,* Dr. B. H. Stone of Burlington. Next year's meeting will be held in Rutland.

Ottawa County (Mich.) Medical Association.—Officers as follows were elected at the annual meeting of this society held in Holland on October 9: *President,* Dr. H. J. Poppen of Holland; *Vice-Presidents,* Dr. A. Leenhouts of Holland and Dr. N. H. Kassaiban of Coopersville; *Secretary,* Dr. E. D. Kremers of Holland; *Treasurer,* Dr. W. G. Winter of Holland.

Southern California Homeopathic Medical Society.—At the seventeenth annual meeting of this organization held in Los Angeles on October 9, officers were elected as follows: *President,* Dr. Francis Kellogg of Los Angeles; *Vice-Presidents,* Dr. Walter Nichols of Pasadena and Dr. J. H. Kirkpatrick; *Secretary and Treasurer,* Dr. F. S. Barnard.

Idaho State Medical Society.—At the meeting of this organization held in Boise on October 4, the following were elected as officers: *President,* Dr. Kleinman of Shoshone; *Vice-President,* Dr. J. C. Woodward of Fayette; *Secretary and Treasurer,* Dr. E. E. Maxey of Boise.

Pensions for Mothers.—A lecturer of the University of Chicago, in a recent public address, advocated the pensioning of mothers by the State. The pension, he said, should increase in amount up to the third child, and then decrease until the advent of the sixth, when it should cease.

For a Koch Institute.—A committee has been formed in Germany, with the Prussian Minister of State as chairman, for the purpose of collecting funds to found an institution in honor of Dr. Robert Koch, on a plan similar to that of the Pasteur Institute in Paris and the Lister Institute in London. It is intended that the institution shall be devoted to research into the means of checking the diffusion of tuberculosis, and that it shall be a permanent memorial of the discovery of the tubercle bacillus by Professor Koch twenty-five years ago.

Tuberculous Cattle on Randall's Island.—The herd of thirty-two cows, the source of the milk supply for the institutions on Randall's Island, New York City, has been found to be infected with tuberculosis and will be destroyed.

Obituary Notes.—Dr. Wm. H. Noble, surgeon to the Western Maryland Hospital at Cumberland, died on October 15 at Narbeth, Pa., at the age of forty-seven years. He was graduated from the University of Maryland School of Medicine in the class of 1883. He resided for a time in the city of Philadelphia, where he was connected with several of the hospitals.

Dr. Henry Joseph Bradley died of heart disease at Philadelphia on October 16, at the age of thirty-eight years. He was graduated from the Medico-Chirurgical College in the class of 1891.

Dr. Thomas A. York of Brooklyn died on October 17 of heart disease, at the age of thirty-eight years. He was a graduate of the Long Island College Hospital, and for thirteen years had been connected with the Brooklyn Health Department.

Dr. Dean W. King of Boulder, Col., died on October 2, at the age of seventy-five years. Dr.

King began practice in Boulder in 1879, and had served as army surgeon with the rank of major in numerous campaigns against the Indians.

Dr. W. S. Laton of Minneapolis, Minn., died suddenly of apoplexy on October 6, at the age of fifty-five years. He was born in Owl's Head, Me., and had practised in Minneapolis since his thirtieth year, making a specialty of diseases of the nose and throat.

Dr. I. C. Williams of Cheboygan, Mich., died on September 27, at the age of fifty-six years. He had practised in Cheboygan for about fifteen years.

Dr. Lila Tenney of Oakland, Cal., died suddenly of heart failure on October 5.

Dr. T. R. Humphrey, said to be the oldest of the pioneer physicians of southern Minnesota, died at his home in Sleepy Eye on October 11, at the age of ninety-four years. Dr. Humphrey was born in Jericho, Vt., and practised medicine for some time in Boston. In 1858 he went to Lacrosse, and six years later removed to Minnesota, settling in Brown County.

Dr. Collister P. Huston died in Challis, Idaho, on October 10, at the age of thirty-five years. He was a native of Boise, and had lived in that city until about five years ago, when he removed to Challis.

Dr. H. A. McSwain of Fayetteville, N. C., died in Rocky Mount on October 8, at an advanced age. He had practised for many years in Fayetteville, and was well known in the northern part of Cumberland County.

Dr. Sigmund Lesser of Davenport, Ia., died of pneumonia on October 9, at the age of sixty years. He had resided in Davenport since 1867.

Dr. M. LeRoy Wenger of Reading, Pa., died on October 1, at the age of fifty-four years, after a lingering illness. Dr. Wenger's father was a physician, and he was a native of Lancaster County. He was graduated from Bellevue Hospital Medical College in 1874, and, after practising for a time in New York, he settled in Reading. He was compelled to give up active work some years ago owing to failing health.

Obituary.

JAMES MAGOFFIN FRENCH, M.D.

SAN DIEGO, CAL.

Dr. James M. French died at San Diego, Cal., on October 7, at the age of forty-nine years. He was graduated in medicine from the Medical College of Ohio, Cincinnati, in 1880, and served as interne in the Good Samaritan Hospital. He practised medicine in Cincinnati for twenty-two years, and then went to San Diego, on account of a pulmonary affection which had afflicted him practically all his life. Dr. French, when in Cincinnati, was lecturer on pathology, then on medicine in the Medical College of Ohio, member of the staff of St. Mary's Hospital, editor of the *Ohio Medical Journal*, and police surgeon. He was author of a widely appreciated "Practice of Medicine," which has reached its third edition. He was an industrious and valuable contributor to many medical journals and medical books. He was president of the San Diego Medical Society.

Dr. French was a man of most lovable personality, of scholarly attainments, and of exceeding uprightness of character. Those whose privilege it was to be counted among his friends have suffered a wound which even time will never wholly heal.

(From Our Special Correspondent.)

OPENING OF THE WINTER SESSION—THE INTRODUCTORY LECTURES—OTHER CEREMONIES AT THE MEDICAL SCHOOLS—OBITUARY.

London, October 4, 1907

The medical schools are settling down for the winter session which was opened with the usual proceeding and enthusiasm. It has been said that one congress is much like another and the same to some extent may be said of the time-honored introductory lectures, though almost always there is something fresh about some of them. Professor Osler distributed the prizes at St. Mary's Hospital and then addressed the students, describing their course of training as a race in which they must make the best use of their mechanism. They had to study science, art, and the man, by which he meant the patient. It was hard to get the right kind of science into the student. If he could only catch him early after absorbing some Greek and Latin he could be trained more quickly. The medical man must get a true perspective of life. An investigating spirit was the life of the physician, and there was no surer way of stultifying it than by the present system of examinations. He had heard that at Edinburgh there were actually seventeen examinations for a student. Let them not think of examination, but devote all their energies to each day's work and the future examinations would look after themselves. He wanted a school of medical pedagogy in which able young men could be trained to teach others. Hospital nurses were now allowed to do things which students ought to do. It was not a question of doing them better, but the student's success in life would depend on their attitude to patients and fellow subjects. Their profession demanded of them devotion, self-sacrifice, and the missionary spirit, a breadth of outlook far above the petty jealousies of life.

Sir Richard Douglas Powell gave the introductory at University College and referred to it as his old school which had been the foundation of all that had come to him in his profession. No stone was left of the old building which, in his day, had seemed so all-sufficient. They were met for the first time in the magnificent building which the enlightened munificence of Sir D. Currie had given them. There had been an attempt to alienate hospitals and medical schools. Sir D. Currie's gift pointed the lesson that a hospital without a school was an emasculated institution with no lesson for humanity at large. The number of students should be regulated by the number of the beds. After his lecture Sir Richard unveiled the medallion portraits of Prof. Christopher Heath and Prof. G. V. Poore. He read a letter from the Duchess of Albany expressing regret at being prevented from attending and hoping on a future occasion to see the portrait of Dr. Poore, who was the adviser of the Duke of Albany, and also to see the school and hospital to which that friend devoted so many years of his life.

At St. George's Hospital there was also an unveiling. In this case a tablet to the memory of the late Dr. Robert Barnes and a new pathological laboratory dedicated to his memory was opened by Dr. Latham, Honorable Secretary to the endowment fund. Dr. Ewart, Senior Physician, delivered the address. His leading note was the growing usefulness and importance of the profession to the State. It was no longer possible to overlook the magnitude of the labors and their indispensable nature for the public good. The duty of the State was to make the utmost use of the profession and its discoveries, to control the prevalence of disease, to study and propagate the culture of health. This work of national defence against degeneracy and disease had been supplied for above a century (since Jenner founded preventive medicine by introducing vaccination), mainly at the expense of the profession without official acknowledgment, support, or subsidy. It was work for a national service with a minister of health at the head and an adequate budget. Immense wealth had been contributed by the profession to the State in the value of lives saved and sickness spared, and this free gift remained unacknowledged, and that although by its work it had curtailed its own means of livelihood. A crisis had arrived directly traceable to the marvelous discoveries in medicine and surgery and the instruction of the public in prevention of disease and the preservation of health. The average income of the British practitioner was from £200 to £250. Reasonable provision for a family and old age could not be secured by this. It was the result of limiting disease and it concerned the State most of all. The first installment of the State's duty had been met in medical in-

spection of schools and eventually the doctor might have to become more and more the servant of the State.

At King's College Dr. Allchin touched the same subject, showing that as the culture of health extended, as preventive medicine became more developed and trusted, the need for medical men would decrease, and then perhaps might be seen the spectacle of a calling destroying the source of its livelihood by its devotion to science and the public weal. He also dealt with the want of uniformity of qualification and condemned the absurd difficulties placed in the way of London students obtaining the degree of M.D. to which the public attached an undeserved importance. It had been hoped that the University of London, now recognized, would have changed this. A wise and comprehensive policy was expected which would have given medical teachers a voice in the regulation and control of examinations and would have opened to London students the legal title of M.D. on satisfactory conditions. But after seven years this had yet to be done. Opportunism and expediency had had their usual result, and the university had lost the great chance it had when starting on its fresh course of becoming the standard qualifying body for London.

At the Middlesex Hospital Mr. A. G. R. Foulerton took up the subject of research in preventive as contradistinguished from curative medicine. No career, he said, was open to a man thus engaged ten or fifteen years ago. Now remunerative offices were open and they would increase in number and value. There had been in the past a reckless disregard of public health, but the average human was being more imbued with the animal stimulus of self-preservation. It was extraordinary that though Englishmen were the first to care for preventive medicine, they were last as a nation to adopt it. For more than fifty years the teachings of Simon, Thorne, and Power had been going on and only now were we looking to the future by providing for the health of the public instead of curing their diseases. He instanced medical inspection of school children in which he heartily believed and pointed out that each school in Japan has its inspector, whereas for the 750,000 scholars in London there are only twenty-one inspectors altogether. The president of the Royal College of Surgeons then distributed the prizes.

At the Women's Medical School Miss Gray gave advice to the students as to acquiring a knowledge of social life and of household and business affairs before beginning professional study. The attitude of the woman doctor to her patients and the public was also considered, with particular notes on her dress, her manners, and her house, all of which had influence. Other questions were also referred to which are quite as appropriate for men as for women doctors. Among them the lecturer said they should know when and whom to alarm. It might be right to frighten friends, in other cases it might be almost criminal to do so. Doctors were often expected to distinguish at once between real and imaginary invalids, but those who expected this did not dream that this was one of the most obscure parts of the territory of disease. Panic on the doctor's part was inexcusable. A demeanor of calm courage was the one with which to face the worst emergency.

The proceedings at the hospitals which have substituted other ceremonies for the time-honored introductory were not wanting in interest, although not exactly of a professional kind. The dinners were such as you would expect. The reception of old students at the London Hospital brought a considerable number to their alma mater to renew former friendships and to notice the still progressing improvements in the buildings and the methods of instruction in the school and the treatment in the wards, etc. Mr. Jonathan Hutchinson was once more present and obliged to make a speech in response to the imperative call of his old friends. Here and at the other hospitals feeling allusions were made to the losses sustained by death among the medical staffs. But as I have already commented on these fatalities as they occurred, I need not refer to them again.

Professor Charles Stewart, F.R.S., Conservator of the Museum of the Royal College of Surgeons, died on the 27th ult. after a somewhat protracted illness, aged sixty-seven. He was a Bart's student and took the M.R.C.S. in 1862. He was president of the Linnæan Society 1890-4, treasurer of the Anatomical Society from its foundation until 1891. From 1894 to 1897 he was Fullerian Professor of Physiology at the Royal Institution. He was elected F.R.S. in 1896 and given the LL.D. of Aberdeen. Before being appointed to the Hunterian Museum he had been connected with St. Thomas's Hospital as a lecturer on physiology and on comparative anatomy and curator of the museum. Then he became Hunterian Professor of Human and Comparative Anatomy and Conservator of the Museum. It is in this last office that the value of his work can be estimated by the splendid series of preparations which he added to those of his predecessors, keeping up the continual growth of the Hunterian Museum. An eloquent lecturer, his addresses were notable for their lucid exposition and clear arrangement.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

SYPHILIS—THE DÜSSELDORF INSTITUTION—PERCUSSION OF THE LUNGS—IMMUNITY AND TUBERCULOSIS—HOMOSEXUALITY.

BERLIN, September 15, 1907.

SYPHILIS and its treatment continues to hold a prominent place in the literature as well as in the discussions before societies. In the Verein für innere Medizin E. Lesser spoke of new aspects in the treatment of the disease. He emphasized especially the effect that the discovery of the *Spirochæta pallida* and the results of animal experiments have had on the treatment. Although Neisser had shown, in experiments on animals, that the excision of the primary lesion was without effect, Finger had demonstrated that the conditions were somewhat different in dealing with the human being. At any rate the diagnosis should be made as early as possible and for this the search for the *Spirochæta pallida* was essential. The data available were still insufficient to give a satisfactory answer to the question as to when the treatment should be begun. It appeared most advisable to commence the general treatment as soon as the spirochete had been found, for since the organisms could very promptly be demonstrated in the blood a general infection was already present and systemic treatment was desirable. This should take the form of long-continued medication with periods of intermission, as suggested by Fournier. For this mercury was to be recommended, although owing to the many undesirable effects of this drug a substitute for it was to be sought.

The opening of the general municipal hospitals and the Academy of Practical Medicine in Düsseldorf comprises an entirely new phase in the development of medicine in Germany. For the first time a German city has designed and built a number of institutions in such a way that, in addition to providing for the care of the sick, they shall also serve for the purpose of scientific investigation and medical instruction. While formerly the State alone has concerned itself with the fostering of medical education, a municipality has now for the first time assumed a similar function. The buildings and clinics include suitable accommodations for the study of internal medicine, electro and hydrotherapy, suction and congestion treatment, light and air baths, radiotherapy, gynecology and obstetrics, diseases of the nose, throat, eye, and ear, acute infections, diseases of children, and dermatology. One building contains sixty rooms for private patients. The lecture rooms and laboratories are equipped in the most complete manner, so that the Academy of Practical Medicine, whose functions will consist mainly in the education of advanced students and in providing opportunities for postgraduate instruction, will no doubt prove very popular. There is still another direction in which the new departure is likely to be useful. Until now the investigations of scientific medicine have been pursued largely on the inmates of State institutions, and this has been possible only in the few places that were the seats of universities. If the example of Düsseldorf is followed in other places large portions of the population who still avoid public hospitals will become better acquainted with these, and in properly conducted institutions will be made available for purposes of scientific research. In this way the number of hospital trained physicians will be increased to the advantage of the profession at large.

In the Berliner medizinische Gesellschaft Goldscheider discussed the percussion of the pulmonary apices. He expressed the opinion that all of the methods so far in use, such as those of Weil, Ziemssen, Gerhardt, and Kroenig, do not map out the actual limits of the lung. These depend on the anatomical conditions and percussion must begin between the two heads of the sternomastoid while the patient changes the position of the arm and the head. It is advisable to carry out the very gentle percussion necessary by means of a glass rod bent at one end and provided with a rubber cap. By the use of this all depressions may be percussed and the intensity and direction of the sound waves may be thoroughly controlled.

The number of serums obtained by inoculations with tuberculous material and recommended for therapeutic purposes is constantly growing. Control observations are therefore particularly desirable, especially when carried out by an authority like Orth. In a paper on the immunization of guinea pigs against tuberculosis he reported on the result of the examination of animals that had been immunized by Friedmann with turtle tubercle bacilli and

which he himself inoculated with human and bovine organisms. The animals immunized against the turtle bacillus all died of human and bovine tuberculosis. Most of them were allowed to live until their death was caused by the disease, but in those that were killed before this time a generalized tuberculosis was found even a comparatively short time after inoculation. The majority of the animals exhibited a typical pulmonary tuberculosis. The average duration of life of the animals that had received the preliminary treatment was 98 days, that of the control animals 113 days. It is evident, therefore, that treatment with the bacilli of a cold-blooded animal is without beneficial effect in the production of immunization.

The well-known psychiatrist, Gudden, has delivered a very interesting address on homosexuality and criminality. He does not regard homosexuality as a disease or manifestation of degeneracy, even although homosexual individuals sometimes present evidences of degeneracy, for homosexuality is common in powerful races, such as the Teutons, Anglo-Saxons, and Japanese. Gudden considers the condition as an anomaly whose behests must be obeyed by its victim. Two groups may be distinguished, one in which the congenital perversity leads to sexual derelictions without external influences, and another in which the craving is first evoked only through example or suggestion. In speaking of the relation between hermaphroditism and homosexuality Gudden said that the hermaphrodite was not always homosexual. Homosexual individuals show their tendency even in childhood, so that the boys prefer to associate with girls and the girls take part in the rough plays and games of boys. The proportion of purely homosexual individuals may be estimated as from 1 to 5 per cent., including bisexual persons, 2 to 6 per cent., so that of the 56 millions of Germans there are probably over a million homosexual persons in all ranks of society. Such figures certainly justify a thorough investigation of the subject.

A PLEA FOR THE SIMPLE SPEECH.

To the Editor of the Medical Record:

Sir:—There is a peculiar tendency on the part of medical men toward the use of involved sentences, polysyllabic words, and unnecessary Latin and Greek derivatives. The people have always recognized this weakness, and scholars have called it "doctors' dog Latin." In a valuable paper on Goiter by Professor Barker in a recent issue of the *Journal of the American Medical Association*, in one paragraph we have the following words and phrases: "Pycnocardia;" "semiotic trinity," and "exquisite thyreotoxic phenomenon." To a man who has made some study of etymology "semiotic trinity" and "exquisite thyreotoxic phenomenon" might have some meaning, a meaning which could, however, be expressed in plain English and be understood by the average man without the aid of an unusually good etymological dictionary. But when we come to "pycnocardia" even the dictionary fails us and we have to fall back on "tachycardia," which is at best a poor substitute for the simple English words "rapid heart beat." As an experiment I read this paragraph to several medical men, among them graduates of McGill and Harvard, and they confessed that they could not grasp its full meaning. Here we have a scientist and teacher who so involves his meaning by the use of complicated verbiage and unnecessary derivatives that he fails to render himself comprehensible.

This note is intended as a modest plea for simple plain diction in scientific speech and writing. The higher one mounts in the realms of true science the simpler do all things become. Simplicity and science are always found together. The most valuable scientific axioms are usually to be expressed in almost epigrammatic form. Generally speaking it may be said that the more words are used the less the meaning is conveyed.

George Franklin Shiels, M.D.

New York.

NUTRITIVE VALUE OF DURUM WHEAT.

To the Editor of the Medical Record:

Sir: Sir James Crichton-Browne of London, in referring to bakers' bread made from blended flours, says that "a small plate of oatmeal porridge is equal to two thick slices from a four-pound loaf." He, of course, has reference to the muscle-making value of two foods, oatmeal containing about 16 per cent. and bakers' bread between 7 and 8 per cent.

There is no sense in a baker's loaf of bread with a gluten content of 7 to 8 per cent. when this country raised this year 60 million bushels of durum wheat that runs in gluten content from 16 to 22 per cent, and which goes into macaroni and is exported to France for French bread. The government, through the Agricultural Bureau at Washington, has demonstrated that from durum flour can be made a loaf of bread superior to any on the market to-day in form, appearance, volume, taste, flavor, and nutritive value (see Agricultural Bulletin No. 70). When the public understands that by asking for durum bread it, in time, can get it and thus receive double nutritive value for its money outlay, the said public will be better off than at present in both pocketbook and health. A little education given by the profession as opportunity presented along these lines would help the cause of dietetic reform mightily.

Charles Cristadoro.

Point Loma, Cal.

Progress of Medical Science.

New York Medical Journal, October 12, 1907.

The "Open Method" Treatment of Cancer.—By this term W. D. Witherbee refers to the following operative method: The patient is prepared for operation in the usual manner, with one exception. Instead of scrubbing the site of the operation, a soap poultice or plain antiseptic dressing is applied and left until the patient is anesthetized. The reason for not scrubbing is that any undue pressure on the tumor or glands may cause some of the elements of infection to be forced out into the surrounding tissue and lymphatics. The dressing or poultice is then removed and potassium permanganate solution poured over the area involved, followed by a solution of oxalic acid. If it is a case with involved lymphatic glands, the operator begins with the most remote accessible lymphatic gland and then clears away all of the glands to the tumor. By beginning with the most remote gland the chances of spreading the infection beyond into the neighboring glands and tissues by pressure on the tumor or glands are lessened. The entire wound is left open and allowed to heal by granulation, thus facilitating an ideal drainage of all the tissues and lymphatics in this region. A dry antiseptic gauze is then applied to the raw surface and the usual dressing placed over this. As soon as the patient is able to submit to it, a fifteen-minute exposure to the Röntgen ray is given daily until the wound is healed. When the granulations first appear in the wound the gauze dressing is removed and a dressing consisting of perforated gutta percha tissue is applied to the granulating surface. Over this is placed a pad of moist boracic acid gauze and over all a covering of oiled silk. This combination affords drainage by capillary attraction through the perforations in the gutta percha tissue into the moist gauze and does away with the tearing loose of those granulations which become imbedded in the mesh of the gauze when it is applied directly to the granulating surface. The oil silk keeps the gauze moist. The advantages claimed for the method are that there is perfect drainage of all the lymphatics and tissues in the infected region, and the change of a deep or subcutaneous growth to an open one. Hence the *x*-ray is better able to thoroughly destroy any remaining malignant elements. The wound takes a longer time to heal, of course, but this is to the patient's advantage, as it helps to insure against a recurrence. Danger of infection from an open wound with good drainage would be slight in a healthy person, for the opsonic index is always high in cases of malignancy.

Surgical Complications and Sequelæ of Typhoid Fever Involving the Gall-Bladder and Liver.—The paper of B. A. Thomas opens with a review of the literature of the subject. He has been able to collect records of 154 cases of cholecystitis in typhoid, including four not previously recorded, in all of which operation led to cure. Notes of these four cases are given. From a table of eleven cases of perforative cholecystitis, it appears that operation saved five. The whole number of perforations in the 154 cases was thirty-nine. In 895 cases of typhoid cholecystitis appeared only in twelve. In making a diagnosis in a given case we are to note (1) whether the accident occurs in the acute course of the fever as a complication, or (2) subsequent to the original infection as a surgical sequel. The symptomatology is considered and the conditions from which the cholecystitis must be distinguished are enumerated as gastric ulcer or cancer, duodenal ulcer, pancreatitis, appendicitis, bowel perforation, renal disease, right lung lesions, lead colic, gastric crisis (tabes), meteorism, echinococcus cysts, and "indigestion." Operation is indicated in: (1) Presence of any symptoms seriously interfering with patient's mode of life; (2) all cases in which medical treatment has failed; (3) acute suppurative cholecystitis or cholangitis; (4) acute suppurative chronic obstruction of the cystic duct; (5) persistence of acute obstruction of the common duct; (6) all cases

of calculus, save possibly that of acute obstruction of the common duct; (7) perforation, and (8) cases in which there is a suspicion of primary carcinoma of gall-bladder. Operation is contraindicated in: (1) Acute obstruction of the common duct or hepatic ducts, in the belief that the stone may pass through the common duct into the duodenum and no others are present to produce a new attack. If fever, however, is associated indicating suppurative cholangitis, operation should be performed with drainage of the hepatic duct; (2) very old or stout individuals or those suffering from diabetes, arteriosclerosis, cardiac, pulmonary, or renal disease; (3) extensive carcinoma of the biliary passages. In contrast to the gall-bladder, lesions of the liver or typhoid calling for surgical intervention are rare. Multiple focal necrosis of the organ in typhoid was found in over 10 per cent. of a series of 2,000 cases. The rarity of hepatic infection may be due to the bactericidal function of the liver cells. The colon bacillus is probably the infecting agent. Arguments in favor of this view are: (1) It is present in liver abscesses in typhoid, (2) the liver promotes its growth while it inhibits the growth of the typhoid bacillus, (3) its virulence is increased by intestinal disorders, (4) when isolated from typhoid stools it is more virulent than when isolated from healthy stools. Symptoms are those of a general infection and a local focal lesion. If a solitary abscess can be made out, the pus should be evacuated. As to whether or not surgical intervention is advisable in cases of multiple abscesses is a debatable question, but the author inclines to the belief that no evil would follow the patient and that drainage would be followed by relief in some cases.

Indications for the Mastoid Operation.—E. B. Dench considers this topic with special reference to the value of the differential blood count and of the bacteriological examination of the aural discharge. He believes that the value of the blood count has been overestimated. The figures in a given series of cases taken at random showed that increase in the polymorphonuclear count did not occur in cases of acute otitis media with mastoid involvement with sufficient frequency to make it valuable as a diagnostic measure. If, however, the lesion has so far advanced as to involve either the brain or its meninges, the blood count may be of value. As to exaination of the aural discharge, smears were found negative in eight out of thirty-seven cases. In eight infection was due to the staphylococcus, in ten to the streptococcus capsulatus, in two to latent streptococcus, in three to streptococcus, in two to pneumococcus and streptococcus, in two to pneumococcus, and in two to pneumococcus and staphylococcus. Out of the thirty-seven cases eight came to mastoid operation. In general, if the examination is either negative or shows only staphylococci, mastoid complications are not apt to occur, but the rule is not invariable. Otologists in general have considered the streptococcus especially virulent and some think that its presence in the discharge, even in the absence of the classical mastoid involvement, calls for opening of the mastoid cells. Several clinical histories illustrate the points made in the paper.

Journal of the American Medical Association, October 19, 1907.

The Delivery of Debilitated Women.—E. P. Davis points out the advisability of resorting to abdominal section in many cases in which it has been largely the custom to depend on other methods. These include not only cases of justominor pelvis, in which attempts to modify the fetal growth are uncertain and unsatisfactory, and the induction of labor dangerous to both mother and child, but also a class of cases in which the mother, although normally formed, is unfit for labor from general debility, constitutional defect or disease, or infection and exhaustion. In many of these cases abdominal section affords the best chances to both mother and child, as by it the dangers of prolonged pregnancy, of exhaustion, laceration, and shock are largely avoided. Abdominal section has also given good results in cases of eclampsia and placenta prævia. In the latter the limitations are narrow, comprising cases of primiparæ with poorly developed and resistant birth canal, and the operation must be done early before exhaustion by hemorrhage. Davis summarizes his consideration of the subject by saying that at present delivery by abdominal section, especially if elective, compares favorably with other methods of delivery for mother and child in debilitated patients.

The Defective School Child.—W. C. Hollopeter considers the present methods of instruction too complex and difficult for the child. There are too many subjects for study, and the requirements as to thoroughness are too rigid. The classes are too large and the personal equation of the child is too much disregarded. The bright child gets the advantage and the backward or defective ones are neglected. The recognition of the power of attention in the scholar is neglected in the grading, of which it should be the basis, and the average teacher does not duly estimate the disabilities of her pupils, but is apt to believe their deficiencies due to wilful inattention and laziness. Such cases are to be found in every school, and a great injustice is done the children by their non-recognition. This is especially true of the depraved type of children, who, for lack of proper attention, largely recruit our criminal classes. The physician should take a deeper interest in observing the mental deficiencies of children in the schools and seeing to their proper classification. Their physical defects, including those of the eye, ear, and nose, should receive more attention than is now given them.

Drug Absorption and Elimination.—E. R. Zemp thinks that physicians do not study their works in materia medica enough, and that they frequently forget or ignore the important actions of drugs. The systemic action of a drug is due to its absorption and the duration of its action is dependent on the rapidity of its elimination; hence the knowledge of the rapidity of absorption and elimination carries with it the knowledge how often to repeat the dose. Physicians should also know the conditions that affect absorption and elimination, the conditions of the circulation, such, for example, as the retarding action of dropsical states which make hypodermic medication dangerous, those of the stomach and intestines, the selective absorbing action of the skin, etc. He reviews several of the commonly used drugs as regards these points and gives his practical therapeutic deductions. In the case of opium, with its rapid absorption, slow elimination, and consequent cumulative action, he condemns the use of large doses, preferring small doses frequently repeated, and insists on the importance in case of poisoning of keeping the stomach free from the drug, as it is largely eliminated into this viscus where it may be reabsorbed. The need of being prepared for possible dangerous effects of cocain administration is also emphasized, as well as the need of care in draining off dropsical effusions in patients who have been taking large doses of digitalis; the danger of even small doses of nitroglycerin, even tasting it being sometimes perilous, and other points of practical importance in relation to cocain, belladonna, chloral, and iodoform are also mentioned.

Carbon Dioxide Snow for Skin Lesions.—W. A. Pusey calls attention to the use of frozen carbon dioxide for the destruction of lesions of the skin or for producing a violent inflammatory reaction in such lesions. He reports two cases of extensive hairy nevus treated by this method with striking results, and one of erythematous lupus apparently completely cured. He has also treated several cases of vascular nevus by this method with success. In cavernous nevi he believes it would succeed only in selected cases. In lupus vulgaris it is ineffective, and the same is perhaps true of epithelioma. This method furnishes a convenient and effective treatment of warts, calluses, senile keratoses, and other such lesions. Carbon dioxide in the liquid form can be obtained in the drums in which it is sold to druggists, and as it escapes from the cylinder it is collected on cloth or chamois skin in the form of a fine snow. This can be compressed and shaped as desired. Its effects depend on the pressure with which it is applied and the duration of the application. By regulating these its destructive action is controllable and can be accurately gauged. With strong pressure, he thinks, freezing to a depth of from one-eighth to one-sixth of an inch can be produced in a few seconds. As a rule, he employs just enough pressure to hold the snow firmly against the skin, but varies this sometimes according to the effect desired. Applications for from five to ten seconds are sufficient to remove thin layers of pigment from the skin or to induce an inflammatory reaction for therapeutic purposes, as in erythematous lupus. If prompt action is desired and moderate scarring makes no difference, a vigorous prolonged single application can be made and the work done at once. If deep destructive action is wanted the application can be repeated on successive days or at longer intervals. Otherwise the application of the snow should not be repeated till the effect of the previous application has disappeared.

The Lancet, October 5, 1907.

Relation of Polymastia to Tuberculosis.—In the course of his investigations on polymastia T. Iwai has considered the subject with reference to the occurrence of tuberculosis and presents statistical results of these observations. He finds polymastia more common among the tuberculous, especially the pulmonary type, than among the nontuberculous. Polymastia occurs nearly twice as frequently among the former as among the latter. On the

other hand, those having polymastia are more liable to be affected by tuberculosis than those who have not. The difference between the two classes is more than 15 per cent. The author's observations were confined to his own countrywomen. Other races might show different proportions.

Acute Lupus Erythematosus.—A case is reported by G. A. Dawson, whose patient was a married woman of forty-three years. Without antecedent history. In June, 1905, a patch appeared in front of the left ear, quickly followed by a patch on the corresponding area on the other side of the head. Six months later the entire face was involved, except the upper part of the forehead and the skin around the mouth and orbits. The eruption was covered by adherent white scales and on the dorsal surfaces of the proximal phalanges were red patches showing dilated follicles filled by horny plugs. Microscopic examination showed a typical lupus erythematosus. In six weeks the left malar region became red and ran with a slight discharge resembling an eczema rubrum. A few days later a symmetrical rash appeared on the backs of the hands, of dull flat red and discrete papules. She was admitted to hospital, but became worse. The temperature rose at night, the scaly areas became raw and bleeding, the areas involved increased in extent and new areas were involved, cough developed, the breathing was accelerated, and albumin appeared in the urine. She died in coma after a stay of one month in hospital. Autopsy showed a semi-solid condition of both pulmonary bases, no tuberculosis, and greatly enlarged kidneys. Other organs were normal. The author notes that cases of this nature have seldom been observed from beginning to end. Erysipelas has been assigned as a cause of this acute phase of the disease, but the remarkable symmetry, the discrete character of the eruption, there being skin of normal color between the papules, the rapidity with which these and the bullæ developed, and the absence of pain or any feeling of even being ill until a few days before the patient's death, are symptoms which bear little resemblance to that affection. So many cases of this acute disease have supervened on the application of an irritant to the chronic condition as to make one hesitate before applying carbolic acid or other strong application where the disease is at all extensive. The general condition was one of acute infection in this case with the regular sequel of septic pneumonia. All the cases of which the author has record terminated in this way.

Note on a Recent Epidemic of Trypanosomiasis at Mauritius.—An account of this epidemic is given by A. Edington and J. M. Coutts, who add an account of their special studies in connection therewith. There seemed to be a doubt as to whether the disease had been imported in cattle from India or whether it was latent in the island named, as a disease had been formerly known to occur there among mules and the symptoms and post-mortem findings bore a striking resemblance to those of the epidemic disease. Experiments to determine whether an animal rendered immune to the Mauritius disease was also immune to the tsetse fly disease were not altogether conclusive as different results seemed to follow in different animals. It seems to be the case that the trypansomiasis in question can exist in goats in a form not readily recognized by blood examination; when indirect trypansomes cannot be seen although susceptible animals inoculated by this blood promptly manifest the disease. An important fact shown by the author's experiments is that it is possible to immunize cattle against the disease caused by the tsetse fly and Mauritius organism, for it establishes the possibility of preparing cattle to act as means of transport in infected areas. The results of the use of the serum from immunized animals are not such as to suggest, in the experimenter's opinion, much practical value.

British Medical Journal, October 5, 1907.

The Limited Value of Diphtheria Antitoxin as a Prophylactic.—O. H. Peters refers to recent epidemics occurring in Nottingham, in one of which he considers the results of the prophylactic use of antitoxin as distinctly disappointing. In one, seven patients developed the disease in spite of the serum out of twenty-one whose throats were proven (by cultures) to be infected by the bacillus. He claims that epidemics are sometimes large, sometimes small, and are susceptible of recovery just as is a disease. As antitoxin is rapidly excreted in the urine, there is a limit to the duration of the immunity conferred. The duration of immunity was at first considered to be four weeks, later three, but Peters believes that this period would be still further reduced. At the end of three weeks, if the epidemic continues, further injections are necessary. Increasing the average immunity dose say 500 units would probably not increase to any extent the duration of the immunity. The author's general views as to the value of the antitoxin as a prophylactic will be understood by reference to the following statements: The procedures, then, of real importance in dealing with an outbreak of diphtheria are two in number, namely (1) bacteriological examination of throats, and (2) isolation of "carriers" of infection under proper medical supervision. Where both of these measures can be systematically carried out, as is possible in most large towns, there is really no necessity for prophylactic injections of antitoxin, the latter procedure being in this case naturally confined to the few whose throats are found to contain the specific bacillus. Even in these "carriers" there is no need to go to the expense and trouble where there is proper medical supervision, that is to say, a daily inspection of throats; for, in the first place, it has been pointed out that nearly all records will show a few cases where membrane developed in spite of antitoxin, the general hospital "carriers" showing a third of such exceptions. Thus the conscientious medical man feels he is in no way relieved from the duty of careful inspection of throats. In the second place, we have such an efficient remedy in antitoxin that there is practically no danger to the patient if the remedy is administered when the disease first declares itself.

Two Cases of Hereditary Dystrophy.—The report on these cases, made by W. Ogilvie and P. G. Easton, concerns a father of 45 years and a son of 25, both natives of India. The father's symptoms began at the age of 25 with a weakness in the shoulders, and have been progressive until now as he is looked at from the front the shoulders and upper parts of the chest seem nothing but skin and bones. There is no known cause for the condition and he has had no symptoms except those incident to the gradual loss of muscular power. He presents a "swaggering" gait, the shoulders being thrown back and the abdomen protruded. This process involves particularly sternomastoid, pectorals, and deltoids. As viewed from behind, trapezius, supra and infraspinatus, senatus magnus, rhomboids, latissimus dorsi and the muscles of the spine. The ribs protruded. The process seemed further advanced on the right side. Upper arms, forearms, hands, and entire lower extremities appeared normal. The son's trouble began at the age of 23 years, two years before he came under observation. In this the symptoms and course were about the same as in the father's case, except that there was a marked lordosis and a peculiar tilt of the scapula. In the son the left side was the one showing the greater atrophy. In neither case was there any history of a preliminary hypertrophy.

Treatment of Yaws.—After some observations on the bacteriology of the disease, A. Robertson details the plan of treatment he has followed in the Gilbert Islands, where the disease is very prevalent. The patients are washed night and morning with carbolic soap, and ung. hydrarg. nit. dil. (1 in 3 vaseline) is then applied to the papules. The ointment serves a double purpose, acting as a germicide and also preventing the flies carrying infection to the other patients in the hospital. In two years' experience the author has not had a single case of yaws arising in the General Hospital, although it is only 60 yards distant from the yaws compound. Potassium iodide is given three times a day in doses of 10 to 20 grains to adults and of 2 to 5 grains to children. Those patients who are anemic or debilitated receive iron citrate or syrup of iron chloride along with cod-liver oil or petroleum emulsion in addition to the iodide. He tried various preparations of mercury at first, but they had no effect whatever on the pains in the limbs or head, which is the principal symptom the patients complain of. The average time the patients are under treatment and till the papules have entirely disappeared is five weeks. Several cases, even those in which the eruption was extensive, have been cured in three weeks. The most troublesome cases are those in which the yaws are on the soles of the feet. Softening the thickened epidermis with sodium bicarbonate solution and afterwards scraping the skin away with a Volkmann spoon is the most expeditious method of treatment. The paresis of the limbs which accompanies or follows yaws disappears rapidly under electric treatment. He has not seen the extensive destruction of tissue and bone which is described by some writers as the accompaniment or sequelæ of yaws, and is inclined to think that there may have been a syphilitic taint in the backeround. Certainly in the Gilbert and Ellice Islands such extensive necrotic processes as necrosis of the palate and nasal bones are due to syphilis and not to yaws.

Berliner klinische Wochenschrift, September 30, 1907.

The Treatment of Angina Pectoris with the Arc Light.—Hasselbach and Jacobaus describe the results

of the application of very intense radiotherapy by means of an arc light of 55 volts and 150 amperes. The patients are placed within a few feet of this and sessions of an hour are repeated at intervals of about five days until about ten treatments have been given. The effect of this very energetic application of the ultra violet rays is to cause an intense degree of dermatitis, accompanied by reddening of the surface, edematous swelling, and moderate tenderness followed by desquamation. In consequence of the intense cutaneous hyperemia the authors believe that the dilatation of the superficial blood-vessels becomes more or less permanent and the attendant lowering of blood pressure affects also the aorta and other deep-seated vessels. Respiration is rendered deeper and less frequent, the mucous membranes become drier, and in some cases a slight degree of mental exaltation is caused. The effects of the treatment persist for months after the last session. Although the method has been applied in a number of other conditions, the authors at present report only on the results obtained in forty cases of angina pectoris. These were all instances of true angina, and in all except one the effect of the light treatment was very favorable. In some of the cases complete euphoria was obtained, in others the improvement persisted for a considerable time, in others it was only temporary. Observations on a considerable series of other forms of organic heart affections have shown that these also are susceptible of improvement by means of the intensive light action.

The Excretion of Mercury by Syphilitics.—Diesselhorst has tested numerous methods of determining the amount of mercury excreted in the urine of syphilitic patients undergoing treatment, and has found that the electrolytic method is both accurate and convenient. The urine is concentrated by heating in vacuo and the organic substances present are oxidized with hydrochloric acid and potassium chlorate. As a cathode a small tube of gold foil 2-3 mm. in diameter and 2-2.5 cm. in length is used. The anode is of platinum. The current used was kept at .1-.05 ampère and the electrolysis was generally complete at the end of one day. The cathode is sealed in a glass tube with the capillary extremity into which the mercury is driven by heat and in which it is weighed. As a result of one series of examinations the author found that mercury appeared first on the fifth day after beginning inunctions, increasing gradually while the treatment continued, and persisting, though gradually decreasing, after its termination until at the expiration of two months after the last inunction only traces were present. The feces at first contained less mercury than the urine, but after the first month after the termination of treatment the feces contained as much or even more than the urine. Traces of mercury could be discovered in the urine and especially in the feces of patients who had had their last mercurial treatment, years before, in the one case as much as ten years previously.

Münchener medizinische Wochenschrift, October 1, 1907.

Krause Skin Flaps in Leg Ulcers.—Chaussy says that in spite of the many methods of treatment at our command for the treatment of obstinate leg ulcers success sometimes seems unattainable and even at the best relapses are frequent. A plan of procedure that does not appear to be as widely used as it deserves is that of the transplantation of thick skin flaps as suggested by Krause. The Thiersch method of skin grafting while often successful primarily does not yield a surface that is resistant enough to stand the wear and tear to which the extremities are exposed, while the Krause flaps appear to possess much greater resisting power. In an instance described by the author in which a large ulcer on the leg of an itinerant carpenter forty-four years of age was treated by this method seven years previously, at the time of writing the result was still a perfect one in spite of the facts that the patient was also suffering from elephantiasis and that several new ulcers had formed as the result of a chronic eczema. Essentials in making the flaps are dry operating, absolute asepsis, and avoiding all antiseptics, only soap and water and tincture of soap being used for cleansing the area to be transplanted and the skin being thoroughly dried with sterile cloths. The flap should be a third larger than the area to be covered, and is held in position by a light dressing of boric acid ointment. The method requires great care and attention to detail, but in spite of the failures that the beginner is likely to encounter it is capable of yielding such excellent results that the author considers that it should be resorted to more often than is at present the case.

Plaster Casts for the Treatment of Flat Foot.—Lengfellner says that the following method is one devised by him for use in Hofta's clinic in order to avoid the drawbacks attending the customary method of taking impressions by means of plaster bandages. The objection to the latter method is that the feet are nearly always more or less distorted by pressure and the resulting casts are therefore inaccurate. Lengfellner has the patient sit on a chair of such a height that the feet swing clear of the floor. A sufficient quantity of plaster-of Paris magma is placed in front of the chair and the patient is instructed to lower his feet into it. Extra plaster is added around the sides and at the heel and when the mass has set the feet are removed. In about five hours the mold is dry, and after soaking it in water for two or three minutes it is filled with plaster magma to make the positive cast. In about an hour the two can be separated by several blows of the hammer on the mold. As soon as the cast is hard enough, the necessary modeling is done on it in order to furnish the guide for the manufacture of the support to be worn in the shoe.

Deutsche medizinische Wochenschrift, September 12, 1907.

The Treatment of Chronic Endometritis.—Turan describes the manner in which he has successfully applied Bier's congestion treatment to this condition. The apparatus used consists of a fenestrated intrauterine catheter having on its stem a disk at the proper distance from the distal end to prevent too deep penetration of the instrument. The catheter is connected by pressure tubing to a Y-shaped coupling by means of which it communicates with a mercurial manometer and with a suction syringe. In order to use the instrument it is introduced into the uterus, which is ordinarily possible without dilatation of the cervix, owing to the fact that patients of this sort usually have a fairly wide cervical canal. A packing of gauze applied over the disk-shaped portion of the catheter prevents the entrance of air into the interior of the uterus. Suction is then applied by means of the syringe and the desired degree of negative pressure is maintained for a period of from twenty minutes to an hour by clamping the rubber tube. Experience has shown that very little leakage takes place even though the patient walks about while the treatment is in progress. The most suitable pressure has been found to be between 20 and 30 mm. of mercury. The treatment is painless and should be repeated every day for fifteen to twenty sessions. The cases must be rather carefully selected and the most suitable are instances of uncomplicated endometritis. Irregular bleeding or severe pain, pointing to recent inflammation, are contraindications. The results of the treatment are said to be excellent, both subjectively and objectively. In the author's cases of chronic endometritis treated by this method the discharge was usually diminished or caused to disappear entirely and the erosion, it is stated, were also favorably influenced.

The Practical Application of the Demonstration of the Spirochæta Pallida.—Arning and Klein, in reporting the results of their work in the examination of the patients in the Hamburg St. George Hospital for venereal diseases, say that they have reached the conviction that the *Spirochæta pallida* is the cause of syphilis and is pathognomonic for the disease when discovered in suspected lesions. The search for this organism should be made a routine in hospital work and in time will also be necessary in the work of the practising physician. The staining method that proved most satisfactory in the hands of the authors was the Preiss modification of the Giemsa stain. One hundred and forty cases of clinical chancres were examined, 112 of these being on the male genitals. In only four instances were the spirochetes not found, the reason in two of the cases being that the ulcers had already undergone prolonged local treatment with mercury. In fourteen primary lesions of the female genitals the spirochetes were discovered in every instance. Only ten failures are reported in 170 cases of syphilitic plaques and patches of various sorts. Seventeen cases of suspected or actual congenital syphilis were examined and in every instance in which clinical syphilis existed the spirochetes were found. In thirty-two cases in which the diagnosis was clinically uncertain the spirochetes were found seven times and the subsequent clinical course was that of syphilis. Eighteen cases gave a negative result and were treated as soft chancres, but in two of these the occurrence of secondary symptoms showed that the search for spirochetes had not been sufficiently prolonged. In the remaining seven cases treatment by mercury had already been administered and no spirochetes were found. In ninety-three cases the clinical picture was that of soft chancre and the examination was made as a species of control; in two of these the spirochete was found, but the others, in which a very careful search failed to detect the microorganism, ran the clinical course of nonsyphilitic affections.

Book Reviews.

The Principles and Practice of Dermatology, Designed for Students and Practitioners. By William Allen Pusey, A.M., M.D., Professor of Dermatology in the University of Illinois; Dermatologist to St. Luke's and Cook County Hospitals, Chicago; Member of the American Dermatological Association. New York and London: D. Appleton and Company, 1907.

This is a new treatise on dermatology, written, however, by one who is well known in the dermatological world and whose experience, not only as a practitioner, but as a teacher, has qualified him for the by no means light task of presenting this subject in a new light. It is rather hopeless to expect that a writer can present anything that will be new to those familiar with the current literature of dermatology, yet it is well when a competent man collects all this mass of undigested material, condenses it, arranges it in readable form, and puts it forth for the instruction of the non-specialist. This Dr. Pusey has done and has admirably done. He has moreover added the personal note which is so grateful in any work of this kind and which gives to it its chief value. Whether his dermatological colleagues will always agree with him in his interpretation of the facts and in his recommendations for treatment is a matter of no moment—it is probable they will differ with him on many points, as the writer of this review does on some; but if his views are based on the teachings of his own experience they are valuable, and so long as medicine is not a fixed science, they are as likely to be correct as those of his colleagues. The author devotes considerable space to anatomy and other first principles, more than we think is necessary, since the student and general practitioner are supposed to be familiar with these subjects, and if they are not, can get all the necessary information from any books on anatomy and physiology. Books are too big these days, and they could well be shortened by omitting unnecessary matter. The classification—that vexed question in dermatology—which the author formulates is excellent in its simplicity. On the whole the book justifies its existence; it is a safe guide for the general practitioner, and contains much that will be found of practical service to the dermatologist as well.

La Tubercolosi. Per Mario Valtorta e Gino Fanoli. Con Prefazione del Prof. Augusto Murri. Milano: Ulrico Hoepli, 1907.

In this pocket manual Voltorta and Fanoli have given a very condensed and practical résumé of what the average physician needs to know about pulmonary tuberculosis. There is a brief but sufficient discussion of the sanatoria and their value, as well as a summary of the modern ideas concerning the relation between human and bovine tuberculosis. The specific sera and vaccines are very briefly touched upon, and the authors are practically non-committal on the subject of Maragliano's specifics. Behring's new vaccines are spoken of, as they deserve to be, as substances still under experimental study. An appendix shows in summary what has been done in Italy to combat tuberculosis.

The Practical Medicine Series. Comprising ten volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M.D. Series 1907. Chicago: Year Book Publishers, 1907.

Volume I. General Medicine, Edited by Frank Billings, M.S., M.D., Head of Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. Salisbury, A.M., M.D., Professor of Medicine, Chicago Clinical School.

But little need be said in reviewing the first volume of the new series of this popular annual. That it keeps up the enviable record made by Dr. Head and his collaborators in former years is a foregone conclusion. The practitioner will find in the pages of this little book all that he wants to know regarding recent advances in the field of internal medicine, especially regarding the opsonic index, the recently applied sera and vaccines, etc.

Volume II. General Surgery. Edited by John B. Murphy, A.M., M.D., LL.D., Professor of Surgery in Rush Medical College, etc.

The arrangement and treatment of the subjects in this volume are much like those in the corresponding volume of the 1906 series. Dr. Murphy's name on the title page guarantees the thoroughness and good judgment which characterizes the work. Much attention, as may be expected, is given to recent work on surgical infections, opsonins, and vaccine therapy; to the study of shock and the modes of preventing and treating it; to abdominal surgery, its methods and modern results, and to malignant new growths, including the trypsin treatment of the latter.

Volume III. The Eye, Ear, Nose, and Throat. Edited by Casey A. Wood, C.M., M.D., D.C.L., Albert Andrews, M.D., and Gustavus P. Head, M.D.

The specialist in diseases of the eye, ear, nose, and throat, or in any of these groups, should welcome this volume of the Practical Medicine Series as it gives him in a small space most of the important features in the development of these branches during the year 1906. Naturally the book will not take the place of current special journals and reviews, but especially for the busy man whose office work fags him so that he must cut his reading down to a necessary minimum, the present volume will prove of inestimable value. It is difficult, even for a specialist, to keep posted on every advance in his line, and this is what the present volume undoubtedly will assist him in doing.

Physical Diagnosis, With Case Examples of the Inductive Method. By Howard S. Anders, A.M., M.D., Professor of Physical Diagnosis, Medico-Chirurgical College, Philadelphia; Physician to the Philadelphia General Hospital, Tuberculosis Department; Late President of the Pennsylvania Society for the Prevention of Tuberculosis; Member American Medical Association, American Climatological Association, American Association for the Advancement of Science, etc. With forty-eight illustrations in the text and thirty-two plates. New York and London: D. Appleton and Company, 1907.

This book is apparently written for the beginner in the study of physical diagnosis. It contains besides the ordinary characteristic physical signs usually described, many minor points not infrequently omitted from textbooks. With all his emphasis of minor, though essential, points in differential diagnosis, the author has avoided the too common fault of verbosity. In laying emphasis on diagnosis by the inductive method of reasoning he performs a service of real value. The student is too apt to make his diagnosis by a comparison of physical signs easily discovered by superficial examination with sets of physical signs taught as characteristic of various diseases in the attempt to make a snapshot diagnosis. The explanation of the characteristics of such signs as tympany, egophony, etc., is short but lucid. All the essential differences between them are mentioned, but only as a guide to recognition during auscultation. There is a very noticeable lack of the "cut and dried" manner of description usually followed, and emphasis is laid rather on the atypical points of diagnosis most frequently observed. The chapter on abdominal examination is short, but comprehensive. Its simplicity and excellent scheme bring out the essential features of diagnosis and furnish all material desirable for a student previous to clinical experience. The illustrations are excellent and sufficiently numerous. A chapter presenting a few hypothetical and recorded cases follows the section on lungs and heart, and illustrates as well as possible, without clinical material, the method to be followed in reaching a diagnosis. The student will find this book very satisfactory, and it is not without interest for the practitioner.

Die Hygienisch-Diätetische Behandlung der Syphiliskranken. Von Dr. Julius Müller, Arzt für Hautkrankheiten in Wiesbaden. Berlin: August Hirschwald, 1907.

Too little attention is paid in the majority of our textbooks to the hygiene and diet in syphilis. For this reason the little monograph of 118 octavo pages which Dr. Müller offers is both timely and useful. He begins with the mental and normal hygiene of syphilitics, passes on to the diet, with special reference to the use of alcohol and tobacco, and then takes up such hygienic topics as the occupation of the syphilitic, the value of baths, waters, climate, the local and general personal hygiene, the prophylaxis of syphilis, and the relation of syphilis to marriage. The book is written in a very clear and well arranged manner.

Manuale Pratico dell' Igienista. Pei Dottori Clemente Tonzig e Guido Q. Ruata. Con Prefazione del Professore A. Serafini, Direttore dell' Istituto d'Igiene della R. Università di Padova. Milano: Ulrico Hoepli, 1907.

This new number in the Hoepli series of manuals deals with a great variety of subjects, and is supposed to contain whatever a sanitary official needs to know in his daily work. It contains chapters on the microscopical, bacteriological, chemical, and physical examination of food, air, water, soil, beverages, on the inspection of foods, on disinfection, and on sanitary statistics. An appendix contains notes on the microscopical diagnosis of rabies. All this is condensed into 360 duodecimo pages of fine print, and while the book is full of information, it deals with many of the topics in such a brief and incomplete manner that one would scarcely expect it to be more than a guide to memory for those who have mastered the subject from larger treatises.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held October 3, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Orthopedic Surgery.

The Joint Cartilage and Its Place in Joint Pathology.—Dr. P. WM. NATHAN read this paper. The joint cartilage was considered to be the primary seat of a number of joint diseases, particularly of a group of joint diseases variously known as rheumatoid arthritis, arthritis deformans, etc. Furthermore, most diseases, whether infectious or degenerative, were supposed to be transmitted to it from either the capsule or the interior of the joint, and thence to the bones beneath. In this wise many diseases which originally affected the capsule were supposed to spread to the bone; and in them the capsular changes were said to be the changes of the early stage, whilst bony changes, ankylosis and the like, were said to be the terminal stages of the same joint diseases. If this was true, the cartilage was either the seat of the original disease, causing both capsular and bony changes, or it was the intermediary between the capsular and bone disease. The question was, did this idea of the pathology correspond to what they knew of the biology of the cartilage, and if not, what was the rôle of the cartilage in joint pathology? Both the physical and morphological properties indicated that cartilage was the most useful agent to facilitate motion. It would retain its elasticity after months of drying if it was again moistened; it showed slight or no signs of irritation if incised and practically no tendency to regenerate if pieces were removed; it remained smooth and apparently normal for months or years in infected joints—even when bathed in pus, so long as there was some motion in the joint; if joint motion entirely ceased it became covered with a layer of connective tissue exactly as in normal joints and the cartilage beneath underwent no change; the connective tisue did not penetrate the cartilage so long as it remained firmly attached, and the bone beneath was normal. In experiments conducted by Dr. Stang and himself, the joint was infected by the injection of virulent staphylococci into the interior of the joint with a view of determining the reaction of the cartilage. The bacteria left the cartilage unaffected in spite of violent joint reaction even when this continued a long time. The bacteria did not grow upon it; they did not invade it nor did they cause proliferative changes in the cartilage cells, no matter how great the irritation. Thus it became evident that the cartilage was decidedly resistant to pathological changes going on within the joint. On the other hand, as the cartilage became immediately affected when its source of irritation was disturbed, separation from the bone caused immediate degeneration and similarly it was brought in sympathy with all the pathological conditions which invaded the bone beneath it. Comparing what they knew of the biology of the joint cartilage and what they learned from experiments with the previously accepted ideas of its use in joint pathology, they were inevitably brought to the conclusion that these accepted ideas were erroneous. The joint cartilage was never primarily the seat of joint disease. It never transmitted disease from the interoir of the joint to the bone. Ulceration, erosion, and degeneration of the cartilage were due to disturbance of its nutrition and therefore due to pathological conditions of the bone; they were not primary and were not due to changes in the interior of the joint. The cartilage did not proliferate in response to irritation of any kind except that of joint motion. Its only reaction was that of degeneration. Hence the exostoses and so-called cartilaginous exostoses could not be derived from the cartilage. Whenever the cartilage was found degenerated it was always due to primary bone disease; when both the cartilage and the capsule were diseased, the capsular disease was secondary and not primary, as hitherto believed. None of the joint diseases had their origin in the cartilage, so that the pathology of the diseases which masqueraded under the name of chronic rheumatism, rheumatoid arthritis, arthritis deformans, etc., was faulty in its inception.

The Relation of Laboratory Aids to Orthopedic Surgery; the Pathological Examination of the Blood, Fluids, and Tissues.—Dr. T. HALSTEAD MYERS said that examinations of the blood were of value to the orthopedic surgeon in making the diagnosis, in determining the general condition of the patient, and in following the course of the disease. An increase in the total number of white cells without any disorder of the blood making tissues, and aside from the physiological leucocytosis following ingestion of food, exercise, etc., would seem to indicate from a clinical standpoint a favorable reaction against infection. Assuming the normal proportion of polynuclear cells to be 75 per cent. and the normal leucocyte count as 10,000, Gibson found that in inflammations which were well resisted the polynuclear cells were increased approximately one degree for every 1,000 of the total leucocytosis above 10,000. But, on the other hand, if there was only a moderate leucocytosis, with a notable increase in the polynuclear cells, it indicated that there was either a severer form of lesion or that there was less resistance to absorption, or that both of these conditions existed. The disproportionate increase of the polynuclear cells was the important fact. He believed that a tuberculous abscess should not be opened unless it became infected, or threatened some important part, or was painful or inconvenient on account of its size. When an abscess was getting somewhat painful, by such a count one could determine whether this was due to tension alone, or to infection. Examinations of the blood showed nothing characteristic in scurvy or rickets. In syphilis there was sometimes a lymphocytosis. The *Spirochæta pallida* had been found in the blood in a very few instances, but only in the primary and secondary stages. While the exciting cause of rheumatism was unknown, there was much reason to believe that some phases at least should be classed among the infectious diseases. There were no characteristic lesions. It was possible, according to Delafield and Prudden, that more than one form of infection was embraced under the designation rheumatism.

The Opsonic Index in Orthopedic Surgery.—Dr. CHARLES OGILVY and Dr. T. HOMER COFFIN presented this paper, which was read by Dr. Ogilvy. The work discussed in the paper was undertaken with the view of determining the opsonic index in cases of tuberculous bone and joint infections; to determine the effect of tuberculin on the opsonic index in these tuberculous cases; to determine the relation between the opsonic index and the general and local conditions; to compare the opsonic indices of ward patients, under tuberculin treatment, with the indices of patients living under the best hygienic conditions, but without the use of tuberculin. The cases under observation were those of tuberculosis of the hip and spine, and brief outlines of the histories were given. The following conclusions were drawn: (1) Tuberculin in small doses, at proper intervals, was of undoubted value in the treatment of selected cases of tuberculous bone and joint infections. (2) The rise of the opsonic index was accompanied by an improvement in the local and general conditions of the patient, if no secondary infection existed. (3) The opsonic index would prove of value in determining the advisability of discontinuing mechanical treatment. (4) The opsonic index was of value in determining the prognosis in tuberculous bone and joint disease. (5) Where there were discharging sinuses and mixed infections the opsonic index might be raised by the use of

tuberculin, without an accompanying improvement of the general or local conditions (specificity).

Skiagraphy in Orthopedic Surgery.—Dr. F. H. Albee read this paper, following it with a lantern slide demonstration. There were certain rudimentary conditions which should be complied with if their interpretations were to be of a sufficiently trustworthy character. First, it was very desirable whenever possible to inspect the plate itself rather than a print. Secondly, care should be taken that the plate was held at a proper distance from the light and that the light was evenly diffused over it. The belief of many pathologists that tuberculosis was nearly always primary in the bone was not, in a large percentage of the cases, confirmed by the skiagraphic findings. It was common to discover first the thickened capsule with a blurring of the outlines of the bony elements of the joints; later the erosion of the articular surfaces, and finally a real destruction of bone. Bone atrophy, not only locally, but in the neighboring bones, could often be detected in the *x*-ray plate, even before atrophy of the soft parts took place. A very important *x*-ray evidence of joint tuberculosis was the marked thinning of the cortex of the neighboring bones, giving an appearance as if their outlines had been penciled and a fine line drawn about them. This was quite diagnostic of tuberculosis. Much could be discovered as to the progress of the disease by a repetition of exposures at intervals. A frequent location for tuberculosis was the phalanges of the fingers; this was frequently confused with a similar syphilitic affection, and the skiagraph was of extreme importance in making a diagnosis In contrasting osteomyelitis with tuberculosis, the latter most commonly affected the epiphyses and articular surfaces, the former rarely did so. An important feature was the absence of marked bone atrophy which was so constant an accompaniment of tuberculosis. The bone lesions which occurred as a result of syphilitic infection were numerous and varied in their manifestations. Of all bone tumors sarcomata were by far the commonest, and the distinguishing characteristics of many of these types could be discovered by the *x*-ray. The skiagraph was absolute in the differentiation of coxa vera, hip disease, and congenital dislocation.

Dr. V. P. Gibney said that as science progressed they must rely more upon the biological, the pathological, and the skiagraphical laboratories as aids in their work. He thought that one of the most important points brought out in the papers was the relation of cartilage to joint diseases. It was a common experience in the operating room to cut into a joint and find the cartilage closed around; yet later the disease would progress just the same; the mistake was in not cutting deeper and searching further. By such aids one would be enabled to make an earlier diagnosis, to localize foci, and thus help greatly in therapeutics. He said he was interested this summer in recalling the ideas of orthopedic surgeons as brought out by continental minds, *i.e.* the correction of deformities and not the prevention of deformities. In this country the aim was always to prevent deformities; the teachings in all our colleges tended in that direction.

Dr. Reginald H. Sayre said they needed the aid of laboratories to help them in differentiating the various forms of bone lesions. The skiagraph was of immense aid in differentiating cysts in the neighborhood of joints which could be easily opened without involving the joint. Great aid could be had by the skiagraph in differentiating tuberculous lesions and synovial conditions. With regard to the value of the opsonic index, they were hardly in a position as yet to know much about it; there were at present diverse results from diverse observers.

Dr. Charles N. Dowd said the aids in diagnosis in the laboratories were so great that at present it was difficult to form a proper relationship between clinical and laboratory observations, and he wondered if they were not in danger of attaching too much importance to the laboratory observations, and possibly not enough to the old-fashioned efforts, such as what we see, feel, and hear. Often they were made to believe the diseased joint worse than it was in truth because of the skiagram. He cautioned against overinterpreting the findings of the *x*-ray. The same might be said of the blood findings. A great many errors resulted from blood examinations, and often one was most startled by the high leucocyte count, especially in children. He was confident that these methods of examination must be made subsidiary to the old-time methods all had relied upon. The opsonic index was as yet in the experimental stage. He felt that it was difficult for them to combine laboratory methods and clinical methods in the right relation.

Dr. Samuel Lloyd wondered if, in the next generation, there would be any old-fashioned methods at all; it was the tendency at present to do away with them. The papers read impressed him with the necessity of a clear judgment brought to bear upon the cases by one who had all his clinical data at hand; the clinical data should be brought in as well as the skiagraph. The opsonic index was not going to be an easy or valuable method of application until they knew how to raise the index. There was a great variability in blood examination, especially when the diseased foci were in closed cavities or in the soft parts. In progressing septic infections they would get a marked increase not only in the polynuclear lymphocytes, but in the other lymphocytes as well. A rising percentage in the lower grade of leucocytes indicated an approaching fatal termination.

Dr. A. Jacobi said that there was not a particle of medical science contributed unless it could be made useful in the interest of mankind, and he wished very much to hear what practical applications were to be made of what he had heard. He believed it would be a good thing if the Academy, as a whole, would take up the subject of the progress and treatment of all these diseases. He would like to know what progress had been made with this new addition to their knowledge of such diseases as they were discussing. Bier's treatment would come in advantageously; many men were now giving attention to this obstructive hyperemia treatment, and Dr. Jacobi was positive that this treatment did good. He then considered the treatment applied years ago as compared with the treatment employed to-day, and impressed upon them the value of phosphorus in bone diseases. Phosphorus had rendered him great service since 1869 when Wagner made his first experiments on the bone of rabbits, fracturing them, giving phosphorus, and noting how they healed the more rapidly when phosphorus was given than when it was not administered. He was positive that osteitis, tuberculous or otherwise, would be better with the internal administration of phosphorus than without it. A great many things that were used years ago should not now be laid aside.

Dr. Nathan, Dr. Myers, and Dr. Ogilvy closed the discussion.

SECTION ON SURGERY.

Stated Meeting, Held May 3, 1907.

Dr. John F. Erdmann in the Chair.

Inoperable Sarcoma Successfully Treated with Mixed Toxins.—Dr. William B. Coley presented these cases. (See page 129.)

Sarcoma of the Orbit.—Dr. Aspinwall Judd presented a boy who was referred to him by Dr. John F. Erdmann for *x*-ray treatment after Dr. Erdmann had given him up. Twenty-five *x*-ray exposures were given with a high tube, at a distance of nine inches to one foot, every five days, or once a week. The treatment was continued from twenty to twenty-five minutes. The boy was never burned.

Dr. John F. Erdmann said the growth was a malignant one of the superior maxilla, and he had removed all but the posterior portion.

Intestinal Obstruction after Appendicitis.—Dr. C. A. McWILLIAMS presented two such cases.

Gonorrheal Rheumatism.—Dr. JOHN ROGERS read this paper. He said that in the treatment with the antigonococcus serum certain facts of general interest had been ascertained. At first, owing to the difficulties in its manufacture, rabbits were used exclusively, but though they were capable of yielding a very effective serum, experience demonstrated that a considerable number of patients suffered unpleasant symptoms after its administration. About one individual in every five or ten was poisoned; that was, within one or two minutes after the injection there followed a feeling of suffocation accompanied by cough, difficult breathing and a bright red flush over the whole surface of the body. At the same time the heart became rapid and feeble and sometimes there was vomiting and involuntary evacuation of urine and feces. The tachycardia, weakness, and general prostration continued in one or two instances for twenty-four hours or more. These peculiar manifestations seemed to depend partly upon the quantity of rabbit serum employed and partly upon the repetition of the dose, or rather the particular time which elapsed between the doses. These peculiarities of rabbit serum, which experience with other analogous products showed were evidently not dependent upon the gonococcic antibody, caused him to urge Dr. Torrey to try another animal and resulted in the use of goats and sheep. The goat serum exhibited a somewhat similar curious toxemia in isolated individuals, and this animal had been abandoned for the sheep, whose serum seemed capable of introduction into the human system with entire impunity up to amounts as large as several ounces at a dose, and in a rather large experience with it he had never noted any of the peculiar "sensitization" phenomena, and there seemed to be no need of anxiety about the intervals between the doses. With a reasonably active serum the average amount of the dose to secure economy, effectiveness, and comfort for the patient was about 2 c.c., or in the neighborhood of 40 minims. This should be given in the loose subcutaneous tissue between the deep fascia and skin in the back of the upper arm, first on one side and then on the other, at intervals of two to six days. The intensity of the local symptoms varied directly with the "activity" of the particular product employed. But if thorough asepsis was maintained and the serum was clear and not contaminated, suppuration would not occur. This local reaction was shortly afterwards followed by an increase in the joint or other symptoms persisting for a few hours and later followed by more or less marked improvement. In the cases treated early in the disease, before there had been time for much effusion or anatomical change, two or three of these injections at intervals of twenty-four, forty-eight, or seventy-two hours might effect a complete cure, but the urethritis, or the original source of the infection, should not be neglected, as the serum had little or no effect upon it, and unless the usual local antiseptic and astringent treatment was energetically carried out a reinfection or recrudescence of the metastasis could be expected. Cases which had exhibited joint symptoms for a few weeks or a month or two might require a dozen or more injections, but in at least 75 per cent. of all the acute, or subacute, or early chronic forms of the disease success might be expected. The failures would be in those suffering from a mixed infection or possibly from one due to a strain of gonococcus not the same as that from which the serum was made. The very chronic or protracted examples of this kind of rheumatism, which might exist for months or years, did not readily recover, and when there existed pronounced deformities, or ankylosis, a cure was impossible. But with perseverance and the judicious use of a satisfactory serum a great deal of good could be accomplished and probably 60 per cent. of these otherwise hopeless invalids could at least be relieved of all pain and signs of active disturbance.

Gonorrheal Rheumatism and Its Treatment.—Dr. JOHN TORREY read this paper. He said that experience had strongly confirmed the opinion that this antigonococcic serum exercised a specific curative influence on a high percentage of cases of certain forms of infection of the gonococcus. After describing the method employed in the preparation of the antigonococcus serum, he called attention to a brief summary of some of the cases of gonorrheal arthritis on which the serum had been used and in regard to which he had been able to collect reports. This list covered seventy cases, in all of which the diagnosis was sure and on whom the serum had received a fair test. These were of all degrees of severity and had lasted from a few days to several years. By the use of the serum fifty-five, or 78 per cent. of these cases were entirely cured, or much improved, and in 15, or 22 per cent., there was very slight or no improvement. Forty-five of these cases, which had received treatment in various other ways for periods of a week to several years, with little or no improvement, were cured or very much improved by the serum. The acute and subacute cases were sixty-one in number. Of these, fifty-one, or about 84 per cent., were acted on very favorably by the serum, while in ten, or about 16 per cent., the result was negative. They had for the most part been running for from two to eight weeks. In those cases in which there was marked swelling, with more or less redness of the joint, the serum acted as efficaciously as in those in which the joint symptoms were less acute. The number of injections which the patients required averaged five. Eleven of them were cured with three or less injections; of these, four were cured with only two injections and one patient with only one treatment. Twenty individuals were cured in ten days or less, and, of these, five in six days or less. The results with the chronic prolonged cases of gonorrheal arthritis had not been as favorable, according to his reports. In nine of these cases, in which the diagnosis seemed to be clear, the serum cured or greatly improved four, or 44 per cent. The other five were benefited slightly or not at all. In all of these there had been an almost continual attack of rheumatism for several years. In such cases the improvement, when it occurred, appeared much more slowly than in the acute ones, and many more injections of serum were necessary. The most reasonable explanation of the failure of the few negative cases to respond to this treatment seemed to be that the infecting agent was a strain of gonococcus of a different nature from any of those used in the production of the serum.

The Prevention of Abdominal Distention after Laparotomy, with Special Reference to the Value of Eserin as a Prophylactic.—Dr. CHARLES A. ELSBERG read this paper.

A New Gas-Ether Inhaler.—Dr. HENRY DAWSON FURNISS demonstrated this instrument. (See Vol. 71, page 775.)

SECTION ON PEDIATRICS.

Stated Meeting, Held May 9, 1907.

Dr. GODFREY R. PISEK IN THE CHAIR.

Exophthalmic Goiter of a Mother Associated with Congenital Malformation of the Heart in Children.—Dr. ALFRED F. HESS presented these cases.

The Indications for and against Removing Adenoids and Method of Operation.—Dr. S. W. THURBER read this paper. The first and large indication for removing adenoids was that they caused nasal obstruction. A second indication was a chronic nasal catarrh, or running nose which might be attended with frequent nose bleeds. A third indication was a stuffy speech. Another in-

dication was a narrowing of the upper jaw and irregular crowding of the teeth. Children were sometimes accused of being inattentive in school when the real trouble was beginning deafness due to blocking of the Eustachian orifices by masses of adenoid tissue. Hypertrophic rhinitis, especially of the inferior turbinate bodies, was another indication. Another indication might be classed under the reflex disturbances, eneuresis, asthma, etc. A large number of cases were on record as much improved or cured by this procedure. Among the contraindications were (1) acute conditions; (2) grave constitutional disease, such as hemophilia, nephritis, diabetes, leukemia, syphilis, or tuberculosis; (3) It was not a good plan to operate during epidemics of the infectious disease. At the Vanderbilt Clinic, during the years from July 1, 1904, to May 1, 1907, there were recorded, in the Department of Nose and Throat, 2,820 operations, and in 52 per cent. of these adenoids were removed. In infants and very young children the use of anesthetics might best be dispensed with, and, in fact, the obstruction was often so large that the use of an anesthetic would be dangerous. After considering the method of operation, he took up a consideration of the results. It could be safely promised that the child would be given a better chance to develop normally, to get better sleep, render it less liable to taking cold and infections, improve its mental vigor and hearing, etc. The child who had already gotten its second teeth, crooked and narrow palate, compressed face, chronic otitis media, the hypertrophic rhinitis would not show the improvement that it would have shown were the adenoids removed months and years before.

Dr. Charles G. Kerley said he had been impressed with the fact that very young children and babies were most subject to adenoids who were habitual suckers. Much could be done in the way of prevention by restricting this habit of sucking, which Dr. Kerley believed to be the starting point of adenoids. Another etiological factor he believed to be "colds." Again, there was a dietetic error to be considered among the causative factors, and this related pretty closely to the overindulgence in sugars.

Dr. B. van D. Hedges of Plainfield, N. J., said that the older one grew the more impressed was he with the rôle played by adenoids in diseases of infancy, and many cases which were obscure were due to the presence of adenoids. The diagnosis should be made with the finger, for the use of the mirror was very unsatisfactory. Once a diagnosis of adenoids was made, the growths should be removed.

Ocular Symptoms and Diseases Accompanying Adenoids.—Dr. Charles H. May said that a certain number of ocular symptoms and diseases occurred with sufficient frequency in children who had adenoids to warrant the assumption of a relationship between the nasopharyngeal and the ocular conditions. These anomalies consisted of epiphora, blepharitis, catarrhal, and more rarely purulent dacrocystitis, congestion of the conjunctiva, phlyctenular conjunctivitis and keratitis, subacute and chronic conjunctivitis, certain forms of conjunctivitis bordering on the trachoma type, and true trachoma. These ocular symptoms and affections frequently accompanied the presence of adenoids, and the removal of the adenoids caused a disappearance of the ocular anomaly in some cases, and in others made the cure less difficult. The adenoids should be considered a predisposing factor rather than a direct cause. They were familiar with the appearance of the mucous membrane of the nose in children affected with adenoids, and the swollen and congested turbinates and the excessive secretion, and also with the fact that these nasal symptoms disappeared without any treatment of the nose after removal of the adenoids. Not only was there apt to be congestion, but the catarrhal inflammation traveled up the lacrymal duct and thus infected the conjunctiva by contiguity. So far as his experience went, rhinitis in infants usually depended upon the existence of adenoids, or of hypertrophied tonsils, or the two combined. The blepharitis, catarrhal conjunctivitis, dacrocytitis, and the phlyctenular affections could be explained in the same manner, the local predisposition produced by the congested conjunctiva. When they studied the structure of adenoids and considered the fact that they were composed of lymphoid material and that trachoma follicles were made up of the same sort of tissue, it was not surprising that the two conditions were often found in the same child. Ever since the Board of Health instituted systematic examination of the eyes of children in the public schools it had been found that a considerable number, fully one-quarter or one-third, were affected with some form of conjunctivitis. Many of those cases admitted of no difference of opinion regarding the diagnosis, and all authorities would pronounce them trachoma. Many others were examples of acute and chronic conjunctivitis; a great many, constituting a considerable proportion of the children of the public schools who were required to submit to treatment of their lids, had a catarrhal conjunctivitis, with more or less follicular hypertrophy; these were the sort of lids which they frequently found in children who had adenoids. These were not examples of true trachoma; no one had ever demonstrated or proven that, if neglected, such cases would produce pannus, ulcers of the cornea, or distortion of the lids, the sequelæ which lead to blindness in true trachoma. The removal of the adenoids in these cases did not appear to influence the conjunctival affection; the latter required local treatment about which, as in the case of diagnosis, there existed considerable difference of opinion.

Relation of Adenoids to Diseases of the Lungs.—Dr. David Bovaird, Jr., said that nasal breathing was detrimental to health. The nose was the natural filter and warmer of the air they breathed, and if the natural channel was blocked and the child forced to breathe through the mouth conditions were established which were favorable to the development of inflammatory processes in both bronchi and lungs. It had always seemed to him that adenoids might be an important factor in the production of tuberculosis of the lungs. In recent years it had been recognized that the presence of adenoids might be an exciting cause of repeated attacks of asthma, and especially in children, and the removal of the adenoids would be followed by the disappearance of the asthmatic attacks. Again there was the effect upon the thorax, which made one more liable to disease; the adenoid growths impaired the respiratory movements and so hindered the development of the lungs. Therefore, whenever adenoids were present that gave symptoms, such adenoids should be removed.

The Question of Adenectomy during Acute Middle-Ear Disease.—Dr. Philip D. Kerrison said that he believed the majority of throat surgeons and otologists were decidedly opposed to the removal of adenoids during acute tympanic disease. In a certain per cent. of the cases operated upon, in which no aural disease was known to have existed, acute middle ear inflammation occurred as a direct result of the operation. The percentage was small, but such cases did occur. In cases of children with acute catarrhal, or acute purulent otitis media, both drum membranes red and bulging, the faucial tonsils moderately, or maybe immensely enlarged, with physical evidences of considerable masses of adenoids in the nasopharynx, the question arose, should they anesthetize the child and incise the drum membrane, wait for the tympanitic inflammation to subside, and place him on the table a second time to remove the adenoids? In deciding this question he said two questions arose: (1) Was the ultimate removal of the tonsil and adenoids an obvious necessity? (2) Would the pharyngeal growth retard or check the tympanitic resolution? If they were of sufficient size and so located as to leave no doubt as to the necessity of

removing them, then there could be little doubt as to their retarding influence upon tympanitic recovery and, in such a case, the child should be placed under the influence of an anesthetic, the drum membrane incised, and the adenoids removed at one and the same time. In support of this he mentioned certain facts, as follows: 1. Either operation, *i.e.* myringotomy or adenectomy, was most successfully done under general anesthesia. By combining the two operations the necessity was obviated of repeated anesthetizations. 2. Adenectomy entailed certain risks to the healthy ear. When the ear was already inflamed acutely it was a favorable time for the throat operation; for by free incision of the drum membrane they safeguarded the ear in a considerable degree from further damage. 3. The free abstraction of blood from the nasopharynx distinctly favored tympanitic resolution. Blood letting from the region of the pharyngeal mouth of the tube was not only rational, but effective. 4. There were undoubtedly many cases of acute otitis media in which recovery was not only tedious and slow, but in the final outcome incomplete until the adenoids had been removed. He agreed with Dr. Thurber that the mere existence of hypertrophied lymphoid tissue in the nasopharynx was not necessarily an indication for removal. The operation was positively indicated only when there were evidences that the growth was interfering with the respiratory or aural function, or causing tissue changes in contiguous structures.

Dr. WALTER E. SPICER said that he always made it a rule in cases of suppurative otitis to ascertain if adenoids were present, and if so to advise their removal. In acute suppurative conditions there was no doubt in his mind but what adenectomy cut short the period of suppuration if done in the early stages, before there had been any destruction of the ossicles and surrounding parts of the middle ear. During the past winter he had operated upon adenoids where there had been a chronic suppuration of several years' standing in 16 cases; all of these 16 were cured.

Dangers of the Operation.—Dr. JOHN J. MCCOY said that where the tonsils were large and not adherent to the anterior pillar of the fauces, or where the adenoids were in clusters and attached to the vault of the pharynx, the operation of removal was very easy. But, if the tonsils were adherent and it became necessary to separate them from the anterior pillar of the fauces, or if the adenoids were distributed over the pharyngeal wall and posterior nasal openings, then the operation of removal was attended with a rather difficult technique. The dangers of the operation he divided into four heads: (1) Traumatism. Many men not conversant with the locality in which they were operating produced an unnecessary amount of trauma. (2) Hemorrhage. Not less than six deaths had been reported, and probably many more that had not been reported, following adenectomies. One should always inquire into the history of hemophilia. Hemorrhage might be due to a fibrous tonsil; the blood-vessels would not properly close. Again unexpected hemorrhage might follow an abnormal distribution of arteries supplying the tonsil and pharynx. (3) Sepsis. Infection of the cervical glands did sometimes occur and might go on to suppuration. Cellulitis of the neck might also occur, as well as retropharyngeal abscesses. Torticollis had been caused by infection of the deep chain of lymphatic glands. (4) Anesthesia and posture. Ether he believed to be the safest anesthetic to use. It was brutal not to give an anesthetic. The best position was the one that gave the greatest freedom of the hands in operating. In the sitting posture the blood was less liable to fill the pharynx.

Adenoids in Epilepsy.—Dr. E. LIVINGSTON HUNT said that the removal of adenoids was followed by improvement in the general health. So far as the results in epilepsy was concerned, all had seen cases where the removal of these growths was followed by a diminution in frequency or of severity of the seizures. On the other hand, all had seen cases not benefited, but at times which seemed to be aggravated, by the removal of these adenoid growths.

Moral and Intellectual Improvements of Public School Children in New York City as a Result of Adenectomy.—Dr. JOHN J. CRONIN said that the psychophysiological feature of education at the present time was gaining ground, and that the educators in this country had taken this up. If a given child did not functionate properly and physiologically in school, there must be something wrong with this child, and he should be referred to the doctor for investigation. The examination of the school children was undertaken with no thought as to its relation to study. The work gradually led up to a selection of men who were up to date in work of certain kinds, and they were surprised to learn the number of children who were "backwards" that had defects of some kind or other. Forty per cent. of the children attending school in Manhattan alone had some of these defects.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twentieth Annual Meeting, Held at Detroit, Mich., September 17, 18, and 19, 1907.

DR. ROBERT T. MORRIS OF NEW YORK, PRESIDENT, IN THE CHAIR.

(*Concluded from page 668.*)

When Shall We Perform Myomectomy and When Hysterectomy in Uterine Fibromyomata?—Dr. JAMES N. WEST of New York said that in 31 abdominal myomectomies which he had performed there had been two deaths, and four of the patients had become pregnant. Taking an equal number of consecutive cases of fibroids treated by hysterectomy, he found that there had been no deaths. For the purpose of comparison, he had looked up his records at the Post Graduate Hospital for three years past, and had found that during that time he did 34 hysterectomies with no deaths, and, adding to this number the six done in other places, it made 40 consecutive hysterectomies in three years with no deaths. These represented the worst cases from those who had come under his care, and all presented symptoms which demanded operation. In one case the chief indication was pain, caused by the pressure of the tumor upon the ribs; yet this woman otherwise was quite well. He had not chosen to present all of his hysterectomy cases, but only took them as they came consecutively for three years, to compare them with approximately the same number of abdominal myomectomies, and this showed that as a general proposition myomectomy was much the more dangerous operation. His average mortality in myomectomy was greater than in hysterectomy, but he thought that, with the more extended experience, myomectomy would show a lessened mortality in his hands, because he had learned what cases might safely have myomectomy, and as his experience had increased he felt that the limits of myomectomy had become narrowed. These cases were cited in detail. After a consideration of the subject from all points of view, he felt that there was no disease to which women were subject in which greater individualization was necessary than in uterine fibromyoma. Those who failed to give this careful consideration to each case, and who adopted the rule to operate as soon as expediency would permit after their discovery, were failing to give their patients scientific treatment.

Enucleation of Large Extramural Intraligamentary Uterine Myomata.—Dr. H. HOWITT of Guelph, Ontario, read a paper on this subject, in which he reported two cases and said that the proportion of intraligamentary myomata that became extramural was greater than that of any of the other varieties. The chief points mentioned in the differential diagnosis between this and the other varieties

were the immovable condition of the tumor, the amount of pelvic involvement, the comparatively rapid growth, the absence of menstrual derangement, and, when the cervix was forced above the pelvic brim, the difference in the length to which a flexible bougie could be introduced on the opposite sides of the vaginal portion of the growth. In the surgical treatment of these tumors enucleation, in his judgment, was preferable to hysteromyomectomy. Enucleation was never contraindicated on account of the size of the tumor or the age of the patient.

Fibroid Tumors Complicating Pregnancy.—Dr. E. GUSTAV ZINKE of Cincinnati reported a case of subperitoneal pelvic fibroid which complicated a four months' pregnancy. Hysterectomy was done, the fibroid enucleated, followed by secondary hemorrhage one week after the operation, likewise a pelvic abscess, with rectovaginal fistula, and recovery. Pregnancy had a twofold effect upon fibroids: (1) With the increased blood supply and the gradual growth of the uterus, the tumor or tumors increased in size. This growth was due to an actual increase in the fibromyomatous tissue as well as a considerable amount of edema. The latter condition was especially well marked in the specimen presented, and because of its semifluctuant consistency gave rise to the suspicion that the pelvic tumor was the uterus, if pregnancy existed at all. (2) Opinions were somewhat at variance as to the effect of involution upon the tumor in case of miscarriage, premature labor, or delivery at term. The immediate effect was a reduction in the size of the fibroid, usually to the dimensions it possessed before conception. While it could not be denied that sometimes the fibroid might be entirely absorbed in the course of involution, in the majority of instances it was more than likely that these tumors not only continued to exist, but began to grow anew after involution had been completed.

Operations for Fibroid Tumors During Pregnancy.—Dr. J. HENRY CARSTENS of Detroit cited seven cases in which he had operated for fibroid tumors during pregnancy, and said that this number, although small, showed that these operations could be performed with safety, although sometimes an abortion occurred. But all things considered, it was far safer than to allow tumors to rapidly increase in size and then interfere with labor. Cases of the latter kind were accompanied by a high mortality. In his series of fibroid operations during pregnancy there was one death. This was preventable, and could hardly be charged directly to the operation itself. The operation is justifiable in certain cases. It is indicated in all instances of fibroid in the lower uterine segment or in the broad ligament. As a rule, fibroids at the fundus need not be interfered with during pregnancy.

Temporary Ureterovaginal Fistula After Panhysterectomy for Fibroid of the Uterus.—Dr. ERNST JONAS of St. Louis, Mo., said that panhysterectomy was preferable to supravaginal amputation as the radical operation for fibroid of the uterus. Empty contraction of the ureter was an important point for differential diagnosis between a lateral opening and complete interruption of the continuity of the ureter in ureterovaginal fistula. Operative interference in ureterovaginal fistula, where there was only a lateral opening in the ureteral wall, was not advisable until there had been a chance for spontaneous healing.

Intraabdominal Torsion of the Great Omentum Without Hernia.—Dr. ROLAND E. SKEFI of Cleveland, O. said that torsion of the omentum was best classified clinically under three simple heads. (1) Torsion dependent directly upon hernia. (2) Torsion in which hernia existed, but the dependence was not clear. (3) Pure intraabdominal torsion. There had been eleven cases of the latter type recorded up to the present time. He gave a résumé of these reports. The twelfth case was that occurring in his own practice. The greatest interest centered about the etiology and diagnosis. Etiologically, four different causes had been advanced to explain the mechanism: (1) External force or pressure; (2) external or internal force acting in conjunction with matting or adhesions on one side; (3) adhesions of the tip with peristalsis of the intestine starting the rotation; (4) circulatory disturbance in the omentum. In the cases given in the literature and the one he reported, the accumulated evidence went to prove that rotation was begun by one of the first three factors, and was carried on to strangulation by the fourth by reason of the over-full veins constantly tending to twist themselves about the shorter, less elastic arteries. In the absence of hernia there was no conclusive diagnostic sign, but suspicion should be aroused if a sudden large mass appeared, not especially sensitive to pressure, doughy in consistence, dull or flat on percussion, and associated with less violent symptoms than one would expect in suppurative appendicitis with the same physical signs.

Fibroid Tumor of the Uterus.—Dr. EDWARD J. ILL of Newark, N. J., reported a case of very large uterine fibromyoma, measuring 24 by 35 centimeters, complicated by a two months' pregnancy, in which nature's attempt at an abortion filled the uterine cavity with blood and thus produced severe pressure symptoms. There was great pain in the left thigh and leg, and both were very much swollen. There was a marked decrease in the pulsation of the left popliteal artery. A supravaginal amputation showed the uterine cavity filled with grumous bloody fluid, with a two months' ovum attached near the right horn. The cavity measured 10 by 12 centimeters. The ovum was dead, as shown by the turbidity of the amniotic fluid and macerated decidua.

Consistency in Aseptic Surgical Technique.—Dr. JAMES E. SADLIER of Poughkeepsie, N. Y., said that operators of equal ability and surgical technique had widely different mortality rates, and asked the question whether at least a portion of this difference might not be due to consistent asepsis on the one hand and inconsistent asepsis on the other.

Deciduoma Malignum.—Dr. MILES F. PORTER of Fort Wayne, Ind., said the majority of malignant growths developing at the placental site were carcinomatous, but some were sarcomatous, and they might be mixed. It would be better to name each specimen according to the microscopic findings. In all types early dissemination by the blood-vessels occurred, hence great care should be used to prevent dissemination by manipulation during operation. Microscopists not infrequently disagreed as to malignancy or nonmalignancy of a given specimen. Specimens removed for examination might show no evidence of malignancy, and other specimens from the same source left no doubt of malignancy. Histologically, all chorioepithelial proliferations were malignant; hence too much importance might be attached to microscopic findings and too little to the clinical. When the latter pointed strongly to malignancy, operation should be done, even though the former were negative. He reported a case occurring in a multipara, aged forty. Twin pregnancy about third month. Menses regular; last one ten days prior to operation. Last period normal except that it began with a gush of blood-stained water. Patient complained of pelvic distress, great weakness, and was very anemic. The tumor was the size of a fist, situated in the hypogastrium, soft and tender. A week later the patient was examined again, symptoms had become aggravated, and tumor increased in size. Two days later fragment removed and pronounced malignant by a pathologist. Panhysterectomy was done, followed by recovery. After operation the uterus was found abnormally large, its walls thick, friable, soft. There were two gestation sacs, one of which was detached. The slides made from the specimen removed were examined by two microscopists. One reported abnormal glandular and decidual proliferation, and the other chorioepithelioma. He exhibited the specimen and microphotographs. The uterus

was abnormally soft, friable, and large, and the woman was seriously ill. The two microscopists agreed in saying that there was abnormal glandular and decidual growth, but one said "malignant" and the other "nonmalignant." The essential nature of the trouble remained in question. There were no signs of inflammation. Nonmalignant glandular and decidual growth with death of cells and consequent autointoxication were a possible explanation. The author thought that chorioepithelioma was the correct diagnosis, and, if correct, the case was unusual because of twin pregnancy and early diagnosis. Increasing experience confirmed the opinion that in suspected malignancy the clinical findings were equally as important and sometimes more important than the microscopical. In his judgment, it was better to have a living patient with an unmade diagnosis than a dead one with a decided diagnosis.

Dermoid Tumor of the Ovary.—Dr. WILLIAM H. HUMISTON of Cleveland, O., reported a case of unusually large dermoid tumor of the ovary, and presented a photograph and a detailed pathological report.

Echinococcus Cyst of the Liver.—Dr. HERMAN E. HAYD of Buffalo reported the case of a man, aged thirty-seven, stonemason by occupation, upon whom he had operated for the removal of a large echinococcus cyst of the liver. The patient made a good recovery.

Conservative Medical Treatment of Salpingitis.—Dr. EDWARD J. ILL of Newark, N. J., made a plea for a nonoperative treatment of salpingitis. He contended that the vast majority of patients with primary attacks got well subjectively, while a goodly number recovered sufficiently to give birth to children, and have a normal puerperium. He deprecated the therapeutic nihilism of the later textbooks, and the unjustifiable desire for operation in the acute cases. He also contended that there was a possible cure of a number of cases of chronic salpingitis with their concomitant pelvic adhesions. He wished it plainly understood that unfortunately many cases needed surgical aid with its mutilating result. Cases that came for medical treatment were, first, the acute febrile conditions resulting from a gonorrheal infection; secondly, those following labor, abortion, and unclean intrauterine instrumentation, and, lastly, the results of inflammatory conditions following tubal abortion, and coming to the practitioner late after the accident. The first and second classes needed about the same treatment, while the treatment of the last was as that for the chronic pelvic adhesions. He advised against medical treatment in cases of abscesses of the ovary, tuberculosis of the tubes, and other rare forms of inflammatory disease. He detailed two cases of gonorrheal infection with extensive pelvic exudates, in both of which recovery and subsequent conception followed. The treatment of gonorrheal pelvic inflammation should be divided into three stages. First, the treatment of the primary infection, the prophylactic. Second, the treatment of the acute tubal and peritoneal inflammation. Third, the treatment of the sequelæ. He advised thorough swabbing of the vagina with a 5 per cent. solution of chloride of zinc. This was usually necessary but once, rarely a second or third time. The vagina should then be filled with a five-yard strip of iodoform gauze, three inches wide, allowed to remain three days. Large hot douches of potassium permanganate, 1-2000, were then ordered. Repeated applications should be avoided, as a rule, since they often proved harmful. Proper hygienic methods were urged. When the case had gone on to an acute salpingitis, the recumbent posture should be insisted on. Pain and temperature demanded an ice-bag above the pubes. This would insure much relief, and opiates could thus be avoided. Nothing would reduce pain and an acute exudate more quickly than the application of cantharidal collodion to the roof of the vagina, made with proper precautions. The application should not be repeated in less than six days, and should be followed in two days by Lugol's solution of iodine and a glycerin tampon. Large hot douches of potassium permanganate were given between the applications. Saline cathartics, proper diet, and freedom from all sexual excitement were ordered. When the acute stage was over, elastic pressure by oakum or jute tampon displaced the glycerin tamponnade. As much pressure should be made as the patient could comfortably bear. Massage of the roof of the pelvis with rubber bags filled with mercury, and introduced into the vagina, was recommended. The patient was placed in a moderate Trendelenburg position, and a second bag was laid over Poupart's ligament, on one or the other side. The séance might last from one-half to two hours, and the manipulation could be done in the office by any well-trained nurse. Recent adhesions and exudates were rapidly absorbed by such treatment, and old adhesions were often stretched and made to yield, so that a more freely movable uterus, tubes, and ovaries resulted. The treatment was not applicable to relapsing attacks of pelvic peritonitis.

Nymphomania as a Cause of Excessive Venery.—Dr. C. C. FREDERICK of Buffalo, N. Y., said that masturbation appeared in three classes of women: First, those mentally and nervously normal, from purely local causes; second, in those of neuropathic taint, hysterics, and neurasthenics, in whom there was perversion of the sexual instinct; third, in those who developed it as one of the symptoms and accompaniments of insanity (occurring here in about 10 per cent.). Judging from the histories of many cases which he had collected, but had not reported in his paper, nymphomania among mentally responsible and nervous women was relatively rare; the mentally irresponsible were more masturbators than given to excessive coitus; and the mentally responsible nymphomaniacs, as a rule, were addicted to excessive venery only when their sexual fall had been early in life.

Nephrocolopexy.—Dr. HOWARD W. LONGYEAR of Detroit spoke on this subject and reported cases in which he had operated during the year. He described at length an operation which he presented before the association last year in a paper entitled "Kidney and Colon Suspension by the Use of the Nephrocolic Ligament and Gerota's Capsule."

Ophthalmia Neonatorum.—The committee on this subject made the following report:

"*Whereas,* A committee has been appointed by the American Medical Association on legislative measures to prevent ophthalmia neonatorum; and

"*Whereas,* It is recognized by this Association that this disease is preventable; and

"*Whereas,* The Health Department of each State is the properly constituted authority for dealing with preventable and communicable diseases; therefore, be it

"*Resolved,* That it is the expression of the sentiment of this Association that definite steps should be taken to secure the enactment of such laws in the various States as shall compel the use of proper measures of prophylaxis by the attendant at every confinement, the execution of such laws to be under the jurisdiction of the State Boards of Health, and we hereby pledge our assistance and cooperation to the committee of the American Medical Association in its undertaking."

(Signed.) R. E. Skeel, O. H. Elbrecht, Magnus Tate.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. E. Gustav Zinke, Cincinnati, O.; *Vice-Presidents,* Dr. John W. Keefe, Providence, R. I., and Dr. W. A. B. Sellman, Baltimore, Md.; *Secretary,* Dr. William Warren Potter, Buffalo, N. Y., re-elected; *Treasurer,* Dr. X. O. Werder, Pittsburg, Pa., re-elected.

Baltimore was selected as the place for the next annual meeting. Time, third Tuesday in September, 1908.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of the State of California.

San Francisco, August 6, 7, and 8, 1907.

ANATOMY.

1. With what sinuses and cavities do the nasal fossæ communicate, and by what means?
2. What structures are supplied by the third, fifth, seventh, ninth, and twelfth cranial nerves?
3. Describe the course of the vertebral arteries, also the formation of the circle of Willis.
4. What nerves supply the muscles of the following regions: Acromial, Anterior Humeral, Posterior Humeral, Anterior Brachial, Posterior Brachial, Radial, Anterior Femoral, Posterior Femoral, Internal Femoral, and Anterior Tibiofibular?
5. Give one example of each of the following named varieties of articulations: Arthrodial, Enarthrodial, and Ginglymus. Describe your examples.
6. Describe the anastomosis in the anterior abdominal wall which is capable of compensating for partial obstruction of the abdominal aorta.
7. Describe the gross anatomy of the kidneys and give their surface markings on the back.
8. (*a*) What apertures are found in the walls of the abdomen for the transmission of structures to or from it? (*b*) At what points are the walls structurally weak?
9. Indicate the surface points for the following: Termination of the spinal cord, abdominal aorta, lowest limit of the pleura posteriorly, bifurcation of the trachea, gall-bladder.
10. (*a*) What anatomical reason is there for dilation of the hemorrhoidal plexus of veins and the superficial abdominal veins? (*b*) Why are varicose ulcers most likely to form on the anterior surface of the leg at the junction of its lower and middle third?

PHYSIOLOGY.

1. Describe the mechanism of the respiratory movements.
2. Discuss in detail the digestive action of pancreatic juice.
3. Describe the red blood corpuscles and give their function.
4. Explain (*a*) the cardiac cycle; (*b*) the nervous control of the heart.
5. Give briefly the physiology of the sympathetic nervous system.
6. (*a*) Where are the trophic centers for the skeletal muscles? (*b*) What is the effect of a unilateral section of the spinal cord?
7. Enumerate the cranial nerves and state whether they are nerves of motion, sensation, or special sense.
8. Distinguish between paralyses of cerebral and spinal origin in (*a*) reflexes, (*b*) nutrition of muscles, (*c*) electrical reactions of muscles.
9. Give the (*a*) function of the submaxillary or submandibular ganglion; (*b*) with its nerve roots and fibers of distribution.
10. Define: (*a*) Atelectasis, (*b*) diopter, (*c*) autolysis, (*d*) dendrites, (*e*) parturition, (*f*) astigmatism, (*g*) aphasia, (*h*) hemolysis, (*i*) cholesterin, (*j*) glycogen.

HISTOLOGY.

1. Describe the histological structures and their relation to each other in a cross section of the wall of the stomach near the pylorus.
2. Describe the histological structure of the kidney.
3. Describe the histological structures and their relation to each other of a mature Graafian follicle.
4. Draw a diagram of a cross section of the spinal cord in the cervical region, showing physiological divisions.
5. Describe the histological structure of the spleen.
6. Name the component parts of a typical medullated nerve fiber.
7. State how you would prepare a piece of liver for microscopical examination.
8. Examination of slides, two specimens.
9. Examination of slides, two specimens.
10. Examination of slides, two specimens.

HYGIENE.

1. Name the sources of contagion in typhoid fever, and state what measures you would suggest to prevent contagion.
2. Upon what findings would you base an opinion of a sample of milk?
3. Describe two methods of purifying water.
4. What diseases may be spread through the use of milk?
5. What diseases would you look for in inspecting cattle at the slaughter house?
6. Name the water-borne diseases.
7. Mention the sources of infection in tuberculosis and describe suitable preventive measures.
8. Describe briefly the efficiency of the common disinfectants and antiseptics.
9. What provisions would you make for ventilating a school room?
10. Describe the rôle of insects in the propagation of disease.

CHEMISTRY AND TOXICOLOGY.

1. (*a*) What is the greatest waste product eliminated by the urine? (*b*) What is the normal amount of urine secreted in twenty-four hours? (*c*) What is the normal specific gravity?
2. (*a*) In what part of the body is dextrose chiefly formed? (*b*) What is its significance, when repeatedly found in the urine? (*c*) In what part of the body is glycogen formed? (*d*) Is it found in normal muscle tissue?
3. Name and describe two separate methods for testing the presence of sugar in the urine.
4. (*a*) What are the pigments in human bile and which is most abundant? (*b*) Are they soluble in water. (*c*) What is the usual composition of gallstones?
5. (*a*) Is there dextrose in the saliva in diabetes? (*b*) Is bile found in the saliva in jaundice? (*c*) Is urea found in the saliva in uremia? (*d*) What is the important ferment in saliva?
6. (*a*) What two enzymes are found in the gastric juice? (*b*) What is the action of each?
7. Suppose you have filtered some urine through a white filter and upon the filter placed a drop of fuming nitric acid. If a yellow spot be formed surrounded by rings of yellowish red, violet, blue, and green, what unnatural presence is indicated?
8. (*a*) Why is egg albumin an antidote for corrosive sublimate poisoning? (*b*) Why should a stomach pump be used after the administration of egg albumin?
9. (*a*) In cases of phosphorus poisoning, what condition of the urine is very marked? (*b*) Would you give oil in a case of phosphorus poisoning?
10. (*a*) Describe a case of nitric acid poisoning and give antidote. (*b*) Under what conditions, when poisons have been swallowed, would you not give an emetic?

OBSTETRICS.

1. Explain how the fetus is nourished during pregnancy.
2. In cases of the death of the fetus during the later months of pregnancy, give diagnosis and treatment.
3. Describe fully the structural and functional changes which normally take place in the heart and lungs of the child at birth?
4. Give in full the diagnosis and differential diagnosis of pregnancy.
5. Give diagnosis and treatment of ectopic pregnancy.
6. Give cause, or causes, prevention and treatment of puerperal convulsions.
7. Describe condition present in placenta previa and how treated.
8. Give diagnosis and treatment of cross presentations.
9. Give causes, best means of prevention and treatment of postpartum hemorrhage.
10. Give causes, best means of prevention, and treatment of puerperal infection.

GYNECOLOGY.

1. In examining a woman per vaginam, name the parts to be inspected or palpated.
2. How do you distinguish between ovarian cyst, fibroid of the uterus, and inflammatory mass in the pelvis?
3. How do you differentiate between erosion of the cervix, laceration of the cervix, and carcinoma of the same in early stages, macroscopically?
4. Give the best method of handling each of the above conditions in brief.
5. How would you diagnose between appendicitis and inflammation of the right ovary?
6. What is the best method of repair of the incomplete laceration of the pelvic floor, and describe it?
7. Describe the best operation for correcting retrodeviation of the uterus.
8. How would you treat tuberculous peritonitis originating in the Fallopian tubes, and what is the prognosis?
9. Which has the greatest effect on the health of the woman, laceration of the cervix or of the perineum, and state why?
10. What is cystocele, and how do you treat it?

GENERAL DIAGNOSIS.

1. Differentiate acute lobar pneumonia and catarrhal pneumonia.
2. Differentiate acute follicular tonsillitis and diphtheria.
3. Diagnose a case of appendicitis by exclusion.
4. What are the signs of danger in general anesthesia?
5. Differentiate cholelithiasis, gastric ulcer, and appendicitis.
6. Make a differential diagnosis between ulcer and carcinoma of stomach.
7. Differentiate chronic parenchymatous nephritis and chronic interstitial nephritis.
8. Differentiate ovarian cyst, fibroids of uterus, and extrauterine pregnancy.
9. Diagnose a typical case of typhoid fever.
10. Differentiate pleurisy with effusion and empyema.

PATHOLOGY.

1. Define inflammation. Describe the process of an acute catarrhal inflammation of a mucous membrane.
2. Name ten pathological disorders of the spleen.
3. Give three synonyms for and describe the gross pathology of chronic interstitial cirrhosis of the liver.
4. How would you recognize the following conditions: (*a*) Macroscopically, (*b*) microscopically; Amyloid degeneration, fatty denegeration?
5. Name the syphilitic lesions affecting the brain and spinal cord.
6. State the blood changes in (*a*) lymphatic leukemia, (*b*) pseudoleukemia lymphatica.
7. Describe the microscopical picture presented in chronic interstitial nephritis.
8. What features characterize malignant neoplasms? Name three tumors generally conceded to be malignant.
9. Differentiate pathology of typhoid ulcer of the intestine, tuberculous ulcer of the intestine.
10. Give the microscopical picture of rodent ulcer.

BACTERIOLOGY.

1. Discuss the value of a morphological diagnosis in bacteriology.
2. Describe the causative agent in thrush and discuss its rôle in human pathology.
3. Name the portals of infection in tuberculosis, gonorrhea, anthrax.
4. Name four acid-fast bacilli.
5. What is the rôle of the colon bacillus in human pathology?
6. How would you diagnosticate canine rabies?
7. What are the causes of difference in the virulence of diphtheria?
8. Outline the serum therapy in bubonic plague.
9. State the nature and the value of antistreptococcic serum.
10. Give the bacteriological diagnosis of actinomycosis.
11. Define symbiosis, antitoxic unit, intermittent sterilization, and mallein.
12. Name six common pyogens, four chromogens, and two obligate anaërobes.

(Answer ten of the above questions.)

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF CALIFORNIA.

San Francisco, August 6, 7, and 8, 1907.

PHYSIOLOGY.

3. The *red blood corpuscles* are biconcave discs, about 1/3200 of an inch in diameter; they are non-nucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin.

Their *function* is to carry oxygen from the lungs to the tissues.

5. "It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves), are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or less extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*." (*Reference Handbook of the Medical Sciences.*)

6. (*a*) The cells of the anterior cornua of the spinal cord and the ganglia on the posterior roots of the spinal nerves are *trophic centers*.

(*b*) In *unilateral section* of the spinal cord there will be: (1) A band of anesthesia, and (2) a band of extreme sensitiveness *near* the level of the lesion; (3) motor paralysis; (4) impairment of muscular sense; (5) reflexes first lost and later (6) increase of knee-jerk; (7) increase in body temperature; all of the above are on the *same* side as the lesion and 3 to 7 are *below* the level of the lesion; (8) loss of sensation on the *opposite* side and *below* the level of the lesion.

8. In paralysis of *cerebral* origin: (*a*) The reflexes are exaggerated; (*b*) the muscles may atrophy a little, but this is due to disuse; (*c*) the electrical reaction is normal.

In paralysis of *spinal* origin: (*a*) The reflexes are either diminished or lost; (*b*) the muscles are decidedly atrophied and wasted; (*c*) there is little or no response to the faradic current and partial or complete reaction of degeneration to the galvanic current.

9. (*a*) The submaxillary ganglion gives off secretory and vasoinhibitory fibers from the chorda tympani to the submaxillary gland.

(*b*) It is connected with the lingual nerve; it communicates with the facial nerve by the chorda tympani, and with the sympathetic. It is distributed to the mucous membrane of the mouth, Wharton's duct, and the submaxillary gland.

10. (*a*) *Atelectasis* is a condition in which the lungs are collapsed or imperfectly expanded.

(*b*) *Diopter* is the unit of measurement for refractive power; it represents the refractive power of a lens at a focal distance of one meter.

(*c*) *Autolysis* is the destructive action of the blood serum of an animal upon its own blood corpuscles.

(*d*) *Dendrites* are the branched processes given off from a nerve cell.

(*e*) *Parturition* is the process of giving birth to a child.

(*f*) *Astigmatism* is a defective refractive condition of the eye, in which rays of light in different meridians are not focused by the eye on the same point.

(*g*) *Aphasia* is loss of the power of expression by speech or writing.

(*h*) *Hemolysis* is the destruction of the blood or blood corpuscles.

(*i*) *Cholesterin* is a crystalline compound found in gallstones, bile, nerve tissue, etc. It is a monoatomic alcohol; composition, $C_{27}H_{45}OH$; constitution unknown.

(*j*) *Glycogen* is a carbohydrate found in the liver, leucocytes, etc.

HYGIENE.

1. The sources of contagion in typhoid fever are food, milk, water, fingers, and flies, or anything that has been in contact with the excreta of a typhoid patient.

To prevent contagion: Keep flies out of the house by means of screens; boil all water and milk used; do not put ice into anything that is to be eaten or drunk; eat no raw food; see that all discharges from the patient are thoroughly disinfected, also all linen or anything that has come in contact with the patient; the nurses or attendants should thoroughly scrub and disinfect their hands after attending to a typhoid patient.

2. An opinion on a sample of milk should be based upon the following findings: Color, odor, taste, reaction, specific gravity, acidity, proportion of fat, total solids, determination of albumin, milk-sugar, ash, percentage of cream, presence of preservatives or other added chemicals, coloring matter, dilution, added solids, pathogenic microorganisms, dirt or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transmitting the milk.

3. Distillation, and boiling and filtration are the two best methods of purifying water.

4. The following diseases may be spread through the use of milk: Tuberculosis, scarlet fever, diphtheria, typhoid fever, cholera.

5. In inspecting cattle at the slaughter house, the following diseases should be looked for: Trichinosis, hydatids, tapeworms, other worms and parasites, tuberculosis, glanders, anthrax, pneumonia, pleurisy, erysipelas, hog cholera, pyemia, septicemia, cattle plague, sheep-pox, charbon symptomatique, malignant edema, foot and mouth disease, actinomycosis, chicken cholera, abscesses, icterus.

6. The water-borne diseases are: Typhoid fever, dysentery, diarrhea, indigestion, goiter, vesical calculi, cholera, scarlet fever, diphtheria, tapeworms, lead poisoning.

7. The sources of infection in tuberculosis are: The sputum of consumptives, prolonged contact with consumptives, tuberculous milk or meat, direct inoculation through broken skin or mucous membranes. Hereditary predisposition may help. Suitable preventive measures would include: Careful disinfection or burning of sputum, etc.; avoidance of spitting in public places; plenty of fresh air and sunlight; an abundance of good and easily digested food; the proper inspection of food supplies; the avoidance of kissing; and reporting of cases to the proper health authorities, and cooperation with them.

8. Burning is the best disinfectant; then moist heat and dry heat; carbolic acid and mercury bichloride are excellent except in the presence of albuminous material, when chloride of lime or formalin are better; formaldehyde and sulphur dioxide are both good disinfectants.

10. Malaria and yellow fever are transmitted by the mosquito; bubonic plague may be conveyed by fleas, flies, and bugs; typhoid fever may be conveyed by flies; tick fever (or spotted fever) is carried by the tick; sleeping sickness is transmitted by a biting fly.

CHEMISTRY AND TOXICOLOGY.

1. (*a*) The greatest waste product eliminated by the urine is urea.

(*b*) The normal amount of urine secreted in twenty-four hours is about fifty ounces.

(*c*) The normal specific gravity is about 1015 to 1025.

2. (*a*) Dextrose is chiefly formed in the intestines during digestion.

(*b*) Diabetes mellitus.

(*c*) Glycogen is chiefly formed in the liver.

(*d*) Yes, it is found in normal muscle tissue.

3. The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1) *Fehling's test*: Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2) *Boettger's test*: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by the dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthaus' *Essentials of Chemistry.*)

4. (*a*) The pigments in human bile are: Bilirubin, biliverdin, bilifuscin, biliprasin, bilihumin; bilirubin is the most abundant.

(*b*) They are not soluble in water.

(*c*) Cholesterin, bile pigments, bile acids combined with calcium, calcium salts, and phosphates.

5. (*a*) Yes, dextrose may be found in the saliva in diabetes.

(*b*) Bile pigment may be found in the saliva in jaundice.

(*c*) Urea may be found in the saliva during uremia.

(*d*) Ptyalin is the most important ferment in the saliva.

6. (*a*) The two enzymes in the gastric juice are pepsin and rennin.

(*b*) *Pepsin* changes proteids into proteoses and peptones. *Rennin* curdles the casein of milk.

7. Bile.

8. (*a*) Because it forms insoluble mercury albuminate.

(*b*) To remove this albuminate before it has time to redissolve in the alkaline chlorides contained in the stomach.

9. (*a*) The urine will be found to contain albumin, bile, bile pigments, biliary acids, and fat.

(*b*) No; because oil would aid in the absorption of the phosphorus.

10. (*a*) There is immediate and acute burning pain in mouth, lips, tongue, pharynx, esophagus, and stomach, chiefly in the epigastrium. There is violent vomiting of a dark and acid material, with shreds of mucous membrane. Yellow eschars are formed where the acid has come in contact with the skin, lips, or tongue.

The treatment is to administer a solution of magnesia or of soap.

(*b*) An emetic is not usually given after poisoning by corrosive acids or alkalies.

OBSTETRICS.

1. *Nutrition of the fetus at different periods of pregnancy*: "(1) At first the ovum absorbs nutriment simply through the vitelline membrane, while passing through the Fallopian tube. The nutrient material is supplied by the secretion of the tube itself, or may consist in part of seminal fluid introduced from without. (2) The vitellus is absorbed by the entoderm lining the umbilical vesicle and alimentary canal, and later it is absorbed and conveyed into the body of the embryo by the blood-vessels of the area vasculosa. (3) When the contents of the umbilical vesicle are exhausted, the chorial villi appear and take up nourishment from the uterine decidua, with which they are in contact. (4) With the disappearance of villi in the chorion leve, the villi of the decidual serotina develop into the placenta, where they take up nutriment from the maternal blood with which they are surrounded." (King's *Manual of Obstetrics.*)

2. *Symptoms* of death of the fetus during the later months of pregnancy are: Cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements cease, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time, crepitus of its cranial bones may be elicited. *Treatment*: Abortion or premature labor must be induced, and the contents of the uterus removed immediately.

5. *Diagnosis*: "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetrics.*)

Treatment consists in removal of the product of conception, by a laparotomy, as soon as the diagnosis is made.

GYNECOLOGY.

5. In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle; there are usually fever, nausea, vomiting, and constipation.

In *inflammation of the right ovary* the pain is not localized, but spreads to the vagina and rectum; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

6. *Laceration of the cervix* may cause hypertrophy, elongation, sclerosis, cystic degeneration, or carcinoma of the cervix; subinvolution, or displacements of the uterus, also endometritis. Other results may be pain on walking, on defecation, or during coitus; sterility or abortion; headaches, backache, neuralgic pains, neurasthenia, indigestion, constipation.

Lacerated perineum may be followed by local tenderness, irritable scar, reflex disturbances, subinvolution of the uterus, rectocele, cystocele, prolapse of the uterus, and incontinence of feces.

Hence laceration of the cervix may be said to have the greatest effect on the health of the woman.

I.

GENERAL DIAGNOSIS.

ACUTE LOBAR PNEUMONIA.	CATARRHAL PNEUMONIA.
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.

Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct; and there is a large area of consolidation.	Physical signs indistinct; and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

2.

TONSILLITIS.	DIPHTHERIA.
1. Sudden onset.	1. More gradual onset.
2. Chill.	2. Chill is rare.
3. Temperature 103° to 105° F.	3. Temperature 101° to 103° F.
4. Vomiting is occasional.	4. Vomiting is common.
5. Albuminous urine rare.	5. Albuminous urine common.
6. Tonsils considerably enlarged.	6. Tonsils not much enlarged unless chronic hypertrophy of the tonsils previously existed.
7. Exudation in spots or a pseudomembrane.	7. Exudation, a thick membrane.
8. Pseudomembrane margins are the same color as the rest of the mucous membrane of the tonsil.	8. Diphtheritic membrane margins are dark red or purplish in color for a distance of a quarter of an inch.
9. Pseudomembrane not adherent; easily wiped away with cotton.	9. Membrane very adherent; removed with difficulty and only with forceps.
10. Leaves no bleeding surface.	10. Denuded surface bleeds.
11. Pseudomembrane does not re-form.	11. Membrane re-forms in a few hours.
12. Pseudomembrane limited to the tonsil.	12. Membrane also found on the pillars of the fauces, the soft palate, and posterior pharyngeal wall.
13. Intense active hyperemia of the soft palate.	13. Soft palate almost normal in appearance.
14. Bacteriological examination shows staphylococci, streptococci, and pseudodiphtheria bacilli.	14. Bacteriological examination shows Klebs-Loeffler bacilli.

(From Coakley's *Diseases of the Nose and Throat.*)

6. *Ulcer of the stomach* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

Carcinoma of the stomach does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

PATHOLOGY.

2. Amyloid degeneration, atrophy, calcification, carcinoma, hyperplasia, inflammation, pigmentation, tuberculosis, syphilis, hyaline degeneration.

3. There are two important forms of chronic interstitial cirrhosis of the liver, hypertrophic and atrophic. The following table (from Thayer's "Pathology") will assist in distinguishing them:

Synonyms. Charcot's, Hypertrophic, Unilobular, Hepatogenous, Biliary.	Laennec's, Atrophic, Multilobular, Hematogenous, Hob-nail liver.
Jaundice. Early and marked, bile often absent from feces.	Late and slight, bile usually present.
Ascites. Late and unimportant.	May be early; often enormous.
Spleen. Enlarged early and markedly.	Late and less.
Alimentary hemorrhage, piles. Not common.	Common.
Liver. Large, smooth, mottled, green.	Small, rough, pale or yellow.
New fibrous tissue. In fine lines and strands between acini and cells, involving all parts equally.	In broad bands, making prominent islands in which the single acinus may appear nearly normal; distributed irregularly.

5. The syphilitic lesions affecting the brain and spinal cord are: Gummata of the meninges, endarteritis and sclerosis of the blood-vessels, meningitis, encephalitis, myelitis, degenerate changes, hemorrhage, and softening of the nerve tissue.

8. Malignant tumors are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

Carcinoma, sarcoma, and epithelioma.

9. In the typhoid ulcer (1) the main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation. In tubercular ulcer (1) the long axis of the ulcer lies at right angles to that of the intestine; (2) it is not necessarily situated opposite the mesenteric attachment; (3) its floor is not smooth nor are its edges undermined, but rather funnel-shaped and irregular; (4) it is not apt to perforate, but it does not tend to heal, rather to spread.

BACTERIOLOGY.

2. The causative agent in thrush is the saccharomyces albicans, or oïdium albicans.

3. The portals of infection in *tuberculosis* are: The air passages, the digestive tract (for food and drink), and any abraded surface of skin or mucous membrane.

In *gonorrhea*: The mucous membrane of the urethra, vagina, eye, and possibly wounds.

In *anthrax*: Through abraded surface of skin or mucous membrane; it may also be inhaled through the respiratory tract.

4. Four acid-fast bacilli: The *Bacillus tuberculosis,* the *Bacillus lepræ,* the *Bacillus smegmatis* and Moeller's grass bacillus.

5. "The *Bacillus coli communis* is a common inhabitant of the intestines of man and animals, being found in the feces, milk, bile, etc. . . . It is also frequently met with in river water and food, so that it is one of the most widespread saprophytic bacteria. Formerly it was thought that the presence of the *Bacillus coli* in water was sufficient proof of its contamination by feces, and thus of its possible contamination also by typhoid bacilli. But recent investigations have shown that there are no grounds for this assumption, as the colon bacillus may reach the water from many different sources. At the same time, in a general way, drinking water found to contain colon bacilli may be regarded as unfit for human consumption.

This organism is associated with many diseases especially of the abdominal organs, though it is not positively known what etiological relation, if any, it bears to these affections. It has been found in peritonitis, appendicitis, cystitis, urethritis, pyelonephritis, etc. The colon bacillus has been assumed to be the cause of cholera nostras and cholera infantum. . . . Puerperal fever is not infrequently due, in part at least, to infection of the vagina or uterus by the colon bacillus. Other diseases to which this organism seems to stand occasionally in relation are endocarditis, meningitis, tropical abscess of the liver, bronchopneumonia, fetid bronchitis, amygdalitis, etc. In these diseases the *Bacillus coli communis* has been found sometimes alone, but usually associated with other pathogenic bacteria in such numbers that it must be considered a factor in the etiology of the affections, and in some cases there is reason for belief that it may be the primary cause. Though further study is required to show the specific pathogenic properties of this microorganism, it is evident that under certain conditions it may become pathogenic to man." (*Reference Handbook of the Medical Sciences.*)

6. When a person has been bitten, the animal should be killed and its medulla taken for careful examination. A small piece of this medulla should be introduced beneath the dura of a rabbit's brain, when (if the case is one of rabies) typical rabies will be produced in the rabbit in from seven to fourteen days. Proper aseptic precautions are necessary in this operation to avoid septic infection with meningitis.

9. "Infection by the streptococcus produces the more severe forms of septicemia as met with in the puerperium, after injuries and operations, in erysipelas, and in association with such specific infectious processes as scarlet

fever and diphtheria. In the latter diseases under these circumstances there is, of course, a double infection. While the theoretical basis upon which the use of this serum rests is quite as good as that of antitoxic serum for diphtheria, the results from its use have not been so valuable, probably because in many instances the infectious process has not been purely due to this microorganism and the other disease organisms have produced their effects uninfluenced by the serum used. The best results have been obtained from its use in puerperal and posttraumatic sepsis, but only in the presence of well-marked and positive streptococcic infection should it be resorted to. Its method of employment is identical with that of diphtheria antitoxin. Care should be taken to obtain the serum from a reliable manufacturer. It would seem probable that in some cases of infectious endocarditis this serum is the best treatment we can use, and in many cases of pulmonary tuberculosis with double infection it may be tried with advantage. The dose of this serum is usually 10 to 20 cubic centimeters every twelve hours, according to the age of the patient and the severity of infection." (Hare's *Practical Therapeutics.*)

11. *Symbiosis* is the necessary association of different kinds of bacteria.

Antitoxic unit is the standard for measuring the strength of an antitoxin. It is the quantity of antitoxin which, on being inoculated into a guinea pig weighing 250 grams, will neutralize one hundred times the lethal dose of toxin.

Intermittent sterilization is a method of sterilization in which successive heatings are applied after regular intervals of time. By this means the spores are allowed to develop into mature forms and are thus more easily destroyed.

Mallein is a substance prepared from glanders bacillus, and used for the diagnosis of glanders.

12. *Six common pyogens: Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus, Staphylococcus cereus aureus, Staphylococcus cereus albus,* and *Streptococcus pyogenes.*

Four chromogens: Staphylococcus pyogenes aureus, Staphylococcus pyogenes citreus, Bacillus pyocyaneus, and *Bacillus prodigiosus.*

Two obligate anaërobes: Bacillus of tetanus and bacillus of symptomatic anthrax.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.

STUDY OF A CASE OF TWO-HANDED SYNCHRONOUS WRITING.

BY GEORGE M. GOULD, M.D.,
PHILADELPHIA, PA.

SUPPOSING the tale to have been true, Newton, I believe, would never have discovered the law of gravitation if the individual apple had fallen on his shoulder instead of on his nose, or if it had not been peculiarly colored, if it had not been blown by an odd gust of wind, or if the philosopher had not turned his ankle that morning, etc. Something individual is needed to bring truth to recognition, and the greater the number of the idiosyncratic elements the more speedily and accurately, probably, will the abstract principle or general law come to light. Generalizing over a lot of malobserved and colorless facts gets us "no forrarder." Being and nonbeing are indeed one, but what kind of a "one," and how useless is such "being," and such "nonbeing?" One swallow may make a summer if a good ornithologist is the observer of the migrating bird. In medicine all wise physicians know there is no "typical case," and that one instance of any common disease studied thoroughly to the bottom, in all its relations and details, is worth more than a hundred glanced at, worth more than all the glittering generalities of the text-books, worth more to the doctor as well as to the patient. The same truth, is it not applicable to physiology, to neurology, and even to psychology? For example: A patient, aged 52, upon whom rests heavy responsibilities, a highly trained civil engineer, cannot think and write at the same time. He can dictate to a stenographer thoughtful and planning letters, but to write the simplest business or even social letter requiring any intellectual attention or phrasing is absolutely impossible. He is under the necessity, therefore, in travel and at home, of having a stenographer about in order that he may answer letters, describe and attend to his work, etc. As a child, he was tortured for years to make him write with his right hand. The natural writing-center in the right cerebral hemisphere was thus rendered atrophic, crippled, or unusable, and the artificially stimulated mechanism in the left side of the brain could never be made to work correctly or easily by the other intellectual organs during the instant in which they had their own tasks to perform.

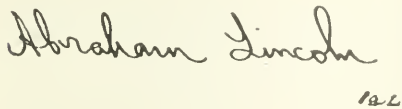
Another patient, a beautiful but sickly and also morbid-minded girl, never could go into society, to balls, dinners, etc., because she could never act naturally, dance, use the knife and fork unconsciously, or in any definite fashion; her eyes, brain, and body had been confused, made awkward and sickly, and her life had become a strange tragedy. The "ambidextral" tyrants had taken away from her, when a child, her natural left-handedness; they had not made her right-handed; she could never, expertly or promptly, do the task or purpose desired; they had also given her lateral curvature of the spine and life-long indescribable misery.

In still another patient, although the tragical aspect had not been so noteworthy, there was found abundant interest in details. She is now left-handed for all except writing. She also cannot write and think at the same time; indeed, she positively "hates to write," and must also dictate to a stenographer a simple description of her symptoms. She is a highly capable and educated woman, a famous teacher, and constantly addresses large audiences on pedagogical subjects with ease—except in regard to certain "slips of the tongue." She frequently transposes words and even parts of words when speaking, immediately becoming conscious of the error and correcting it promptly. These transpositions began at the age of 13, after long and severe training ("with great agony"), had forced her to disuse the left hand for writing; she began asking for, or speaking of "mish and filk," for instance, instead of "milk and fish." Words with an opposite meaning are still used, as *warm* instead of *cool*. "West bay" instead of the intended "best way" will be uttered. If she has something in each hand she will lay down the wrong one, or throw that she wishes to keep in the waste-basket. The greater the general fatigue the more frequent such mistakes. Each eye is equally dominant, *i.e.* the pencil throws two equally-clear images on the wall. At about the age of 17 she discovered that she could write with either hand, and synchronously with both, normal, or mirror-style, with one or with the other, etc. I append a series made recently to illustrate (pp. 718-720).*

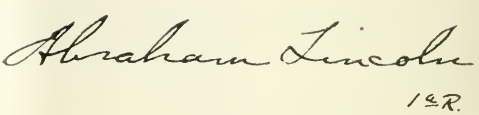
In order to get a clear understanding of the teachings of the case I report, and of other similar ones, one must hold in mind several facts, and the most important is that there is no adequate knowledge of the significance of a biological structure except historically. Secondly there is no history so exact and so illuminating as that given in the most comprehensive of all biological laws, "the ontogeny repeats the phylogeny." That sentence is the master-key of almost all the mysteries of living things. The statical or anatomical phasing gets its explanation only through physiology, becomes clear only genetically. All pathology is in origin nothing more than aberrant and morbid physiology, and all organic structure is the product of precedent and repetitive function. There is no "pod" without a preceding pseudopod. Instead of the common scientific nonsense that there is no inheritance of acquired characteristics, the truth is that there can be no inheritance of any characteristics except acquired ones. To come to details, the eye as an organic structure appears defined within a month after concep-

*In all such bimanual writing it is to be noted that the pens were placed on the lineless blank sheets with gaze and attention, although the movements were subsequently executed without these guides. The spacial and topographic accuracy were thus better than would have been true under other conditions.

tion; the differentiation of muscular tissue only at five months; righthandedness (or lefthandedness), however, commences to appear only fourteen months after conception, *i.e.* about five months after birth. If, therefore, the individual organism epitomizes and illustrates the history of all the ancestry, there are certain psychological and metaphysical conclusions which no monistic or other materialistic logic can escape. Embryologically, the eye is an extension of the brain; the brain comes out to see. It is not so of any other organ of the body. The eye precedes the appearance of muscular tissue by some four months; the inference is unavoidable that the perfection of visual function long antedates and conditions free motility, which is itself the condition of the existence of all higher organisms. *Ubi motus, ibi visus est.* That is the greatest of the Darwinian factors, strangely ignored by all Darwins, governing the survival of the fit and the exclusion of the unfit. A foreseeing and purposive planning of the mechanism of vision, and of motility, is thus evident, and there cannot be foresight and plan



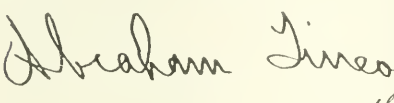
1aL.



1aR.

No. 1*a*L and No. 1*a*R illustrate the natural ordinary single-hand, or discrete, writing, each made under the influence of the visual (which also includes the central, mental, or intellectual) attention. In each case the writing is equally clear, equally respecting the laws of symmetry, and equally correct in topography, direction, localization in space, etc. The slant of the letters, a visual result, is in each case that common in dextromanual writers, and in sinistromanual writers. It should be borne in attention that these slantings of the individual letters are in occidental nations dictated by visual function and, when unconscious, are always present; they are preserved even in the most peculiar or abnormal of the tests to follow.

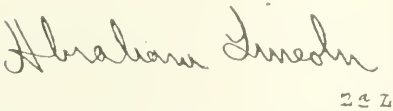
The origins of these slants I have set forth elsewhere. Noteworthy in the illustrations above is the fact that the sinistromanual writing does not fill the allotted 3 3-8 in., but is condensed laterally, not vertically, so that relatively the object occupies only about three-fourths of the longitudinal space taken by the dextromanual writing. It must not be forgotten that the "patient" or "subject" was congenitally lefthanded, but by practice and lifelong habit a dextromanual writer. The preservation, under these circumstances, of a sinistromanual proficiency equal to that of the dextromanual is significant, both for the neurologist and for the "ambidexterity" societies.



1bL

1bR.

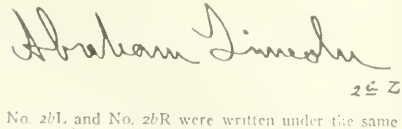
No. 1*b*L and No. 1*b*R, also written separately with closed eyes, bring out the effects of the absence of visual attention. Central attention alone appears to be at best a somewhat vague and inaccurate representation and product of visual attention, yielding want of sense of direction (slanting of the left line upward, of the right downward to an equal degree), and relatively equal inaccuracies in the forms of individual letters in both samples. That the topographic or spacial sense is the direct product of visual attention is again suggested by the fact that, without its aid, the central attention reverses the result seen in 1*a*L and 1*a*R, as to filling of the allotted longitudinal or lateral space. With the left hand (right cerebral center) it fills the entire space, with the right hand (left cerebral center) only about three-fourths is occupied. Lack of the influence of the acquired and inherited visual attention has therefore generally an effect in laterally contracting the space-content in the acquired dextromanual habit, and correspondingly enlarging that of the congenital and disused sinistromanual habit. The inheritance of spacial sense of all past ancestors requires the instant's influence, in the act, of visual attention to insure the best accuracy.



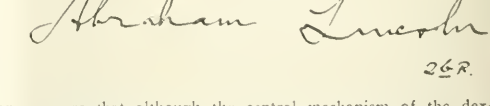
2aL

2aR

No. 2*a*L and No. 2*a*R are synchronous writings, under the influence of visual attention (which includes central attention) upon the forms made by the dextral hand. The sinistral is here the hand of nonattention; let us call it *The Trailing Hand.* Although for writing it is the lifelong habitually disused hand, it was the one first used and habited in writing, and its central mechanism in the right cerebral half brain has preserved perfection of function, despite disuse, and "trails" more perfectly than the dextral in the next example, 2*b*R. The lateral space is again less completely filled by the sinistral hand, although it is the "trailer."

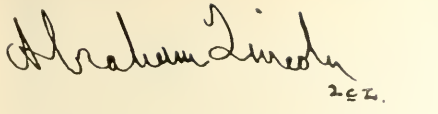


2bL



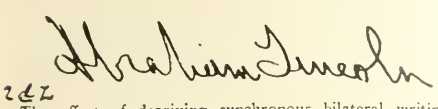
2bR.

No. 2*b*L and No. 2*b*R were written under the same conditions as No. 2*a*L and No. 2*a*R, i. e. synchronously without visual attention, but with visual and central attention fixed upon the sinistral movements, the dextral hand being the trailer. The sinistral space again is not filled; the accuracy and perfection of the writing of the sinistral is a little better than in No. 2*a*L, but the noteworthy fact appears that although the central mechanism of the dextral hand has been the life-long habitually functional one, its natural repugnance, unfitness, etc., is shown when it is deprived of the factor of visual and central attention, the individual letters being generally slovenly formed, the i not dotted, etc. It trails worse than the sinistral despite its education.

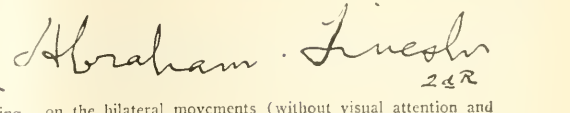


2cL.

2cR.

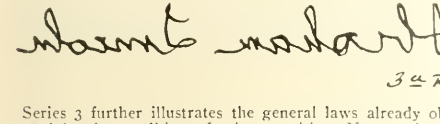


2dL

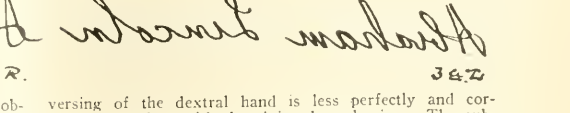


2dR

The effect of depriving synchronous bilateral writing of visual attention is shown in 2*c*L, 2*c*R, 2*d*L, and 2*d*R. In the 2*c* series central attention was fixed upon the dextromanual movements, the sinistral hand being the trailer. In the 2*d* series the central attention is fixed upon the sinistromanual movements, the dextral hand becoming the trailer. In both cases the sinistral writing is the more condensed laterally. The effect of synchronously carrying on the bilateral movements (without visual attention and only with mental attention) is not so bad upon the sinistral as upon the dextral writing, even when the sinistral is the trailer and the dextral has the advantage of central attention. No amount of habit or usage abrogates the primal trend towards lefthandedness or makes the acquired writing expertness of the dextral hand equal to it.

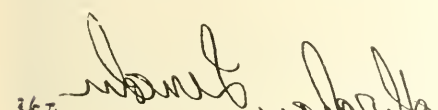


3aR.

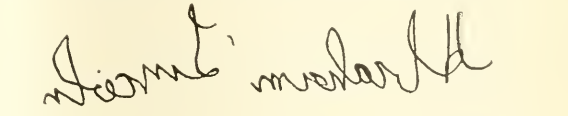


3aL

Series 3 further illustrates the general laws already observed by the condition of mirror writing. No. 3*a* shows the ability of this subject to write with either hand, alone, and with visual attention directed to the movements. By looking through the paper, back to the eyes, or by the use of a hand mirror, one sees that the mirroring or reversing of the dextral hand is less perfectly and correctly done than with the sinistral mechanism. The subject says of this that with the sinistral hand the reversal is "done easily, rapidly, and automatically," while with the dextral hand it is carried out "with difficulty and slowly."

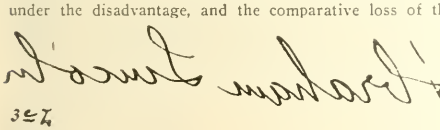


3bL

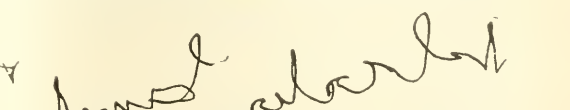


3bR.

The effect of the deprivation of visual attention upon mirror writing shown in 3*b* series further illustrates the foregoing suggestions. Each is written separately, and by the aid of central attention only. "The right reverses just as badly" as in the case immediately preceding. The sinistral hand does its work far better than the dextral under the disadvantage, and the comparative loss of the sense of direction and space-relation is strikingly manifest. For the first time is shown the tendency, slight in the sinistral hand, marked in the dextral, towards a declination, and a double one, of the two words, from the right to the left, *i. e.* in the direction in which the mirror writing proceeds. The sinistral writing is again the more condensed.

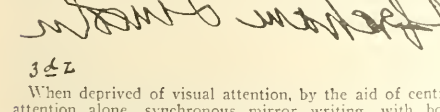


3cL

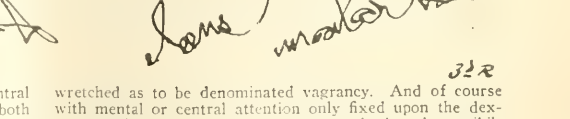


3cR

The complications of the problem, as well as of the interest, increase in the remarkable (unique?) ability of this subject to execute mirror writing with both hands synchronously. The results are shown in 3*c*L and 3*c*R, written with the visual (and central) attention fixed upon the movements of the sinistromanual pen. The trailing dextral is the worst so far in all respects—either as to formation of the letters, declination, and even overlapping of the lines from right to left, and overrunning of the space both lateral and vertical. The topographic or space-limits are little recognized or observed, and character or individuality of the writing is lost. But here arises the most noteworthy and significant statement of the subject: "I find that I cannot execute what would be the logically preceding series, *i. e.* when the mind is fixed upon the right-hand movements. *They will not go.*" Nature flatly balked and refused to budge. Motion was entirely inhibited with the attempt at two-handed mirror writing when visual attention was fixed upon the dextromanual movements. Such writing could only be carried out when the dextral was the trailing hand. In this case there was, therefore, sufficient perfection of the dextromanual mechanism to trail, that is, to act, and badly, as an automaton, by the aid of the more perfect, though disused initiative of the sinistromanual one. To initiate was impossible when it had to supply subordinate directing force and control to the trailing sinistral hand.



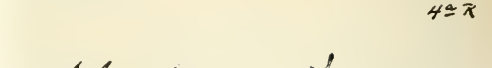
3dL



3dR

When deprived of visual attention, by the aid of central attention alone, synchronous mirror writing, with both hands again repeats and accentuates the preceding conclusions. This is shown in 3*d*L and 3*d*R. Again the central attention is fixed upon the left-hand movements; the right is still able to trail, but notice the lateral concentration of the two words deprived of the control of visual attention, the degradation of form of all the letters, almost to indecipherability, the sharp declination of the line-direction from the dextral to the sinistral side, etc. The space-sense or topographic consciousness is nearly lost. The trailing has become so inaccurate and wretched as to be denominated vagrancy. And of course with mental or central attention only fixed upon the dextromanual task there is even a more absolute impossibility than in series 3*c* of executing any legible or orderly movements whatsoever. "They will not go." But even when deprived of visual attention the central attention upon the sinistral hand is able to make fair copy, and to do much toward helping out the trailing dextral. No amount of use and education could give the dextral mechanism the initiative and effectiveness retained by the thirty-five-year-long disused sinistrocerebral centers.

4aL



4aR

The task remained of writing synchronously with both hands, normal style with one hand, mirror style with the other. No 4*a*L and No. 4*a*R is the first illustration, made with visual attention fixed upon the dextromanual movements. In this case the dextral hand writes normal style, the sinistral mirror style. The trailing sinistral line climbs a little as it moves onward, but the character, accuracy, etc., are well preserved in both.

4bL

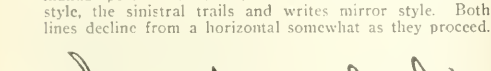
4bR.

In Nos. 4*b*L and 4*b*R the visual attention is fixed upon the sinistral hand; the dextromanual writing is in normal style, the sinistromanual in mirror style. The writings are synchronously executed. That of the dextral hand is more incoordinate, tends still more than before to overrun the lateral limits, ascends as it proceeds, etc., but both are easily legible. The superior initiative and controlling power of the dextrocerebral mechanism is reexemplified.

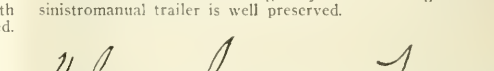
4cL

4cR

Nos. 4*c*L and 4*c*R repeat Nos. 4*a*L and 4*a*R, with the exception that the movements are deprived of the guidance and control of visual attention. The tasks are synchronous, of both hands, and the central attention in this instance is fixed upon the movements of the dextromanual pen. The dextral hand leads and writes normal style, the sinistral trails and writes mirror style. Both lines decline from a horizontal somewhat as they proceed. Although the mental attention is upon the dextromanual movements, the sinistral hand restricts its work to normal and usual lateral limits, while the difficulty of its task, in originating and controlling the trailer, seems to make the dextral lose the sense of space limits heretofore observed. But even here the legibility of the writing of the sinistromanual trailer is well preserved.



4dL



4dR

In Nos. 4*d*L and 4*d*R the conditions of the last test are observed, except that the central attention is fixed upon the sinistromanual movements. The level of the lines is better kept; legibility of both writings is good; the lateral limits of space are preserved or exceeded in the same way as in 4*c*L and 4*c*R.

5aL

5aR

In Nos. 5*a*L and 5*a*R the sinistral hand writes normal style and the dextral writes mirror style synchronously. Visual attention is permitted and fixes the sinistromanual movements, which climb a little, but which result is legible writing. But the associated ones of the trailing dextral hand become almost illegible and have lost nearly all sense of orderly topographic consciousness. As in the 3*c* series the subject again explains that "it will not go with the visual attention fixed on the right-hand movements." The stint was found impossible. And of the greatest significance is the further statement that "this form of reversal was always the least satisfactory, and is not now so good as it used to be." Later, upon request, Miss K. writes: "Some time before I was twenty I discovered that I could do this reverse writing, and since then I have occasionally amused my friends by doing it, but very seldom. Until I did this for you it is surely five years since I last tried it. I did not notice the inability to do this particular specimen less well until I tried it this time for you. I have no specimens written in the past." The coordination of the two cerebral hemispheres is therefore losing an acquired function or aspect, and reverting to a desirable and natural singleness or monolaterality. Confusion, awkwardness, inhibition, indecision, or imperfection of function must follow decision or action initiated or controlled by centers cooperating from different sides of the cerebrum.

5bL

5bR

[illegible] illegibilty and loss of the sense of spacial relations is shown in Nos. 5*b*L and 5*b*R, written under the conditions imposed in 5*a*, except that the sinistromanual movements were deprived of the help of visual attention. Of course it was again wholly impossible to write anything whatever when the mental attention was fixed upon the dextromanual writing movements.

except there is a foreseer and a planner. Mentality, therefore, preceded and created structure. The mind, the life, the brain, the eye, made their tools.

Again, the appearance of slight righthandedness is five months after birth, and its perfectibility goes on throughout life. This particular differentiation of function is dependent upon attention, and is a matter of education. But there can be no attention without an attender. In sensation-making, in conscious willing to act, in choosing to use one hand rather than the other, we reach beyond the limit of automatonism or of mechanism *per se*, and come to the hand upon the lever of the engine, *i.e.* upon the something beyond the machine—in a word, upon the metaphysical. If there is a control or force, called attention, that can be transferred from one side of the brain at will, and markedly change the functions of one side or the other, then there is something outside of and above the individual mechanisms and centers which is not a part of them, and which uses them as tools. A player on the piano is something different from the piano itself. The player upon the cerebral piano transfers his attention to one side or other of the keyboard of the brain. The fact of attention, transferred at will to one part or another, and choosing at pleasure not only the music to play, but the parts of the keyboard on which to play, playing better with one hand or the other—all this demonstrates that there is a mechanism, a material, neurological mechanism, but also that the player is something other and different, placed over it, a mental somewhat not bound up with it, not explainable as the action of the nervous system *per se*, but using that mechanism as an instrument. The psychology that is monistic, that denies life, that denies the fundamental distinction and existence of a machine and a machinist, is *al initio* unscientific.

Moreover, cerebral tumors and traumatisms and physiological experiment have absolutely proved that the adult, central, or cerebral mechanisms of memory, of language, of writing, of speech, etc., are located in one side of the brain, that opposite the writing hand. In the righthanded the left half-brain is therefore preeminently the seat of the mind. The mechanisms that give the man external validity, that intermediate him with useful objectivity, are one-sided. But this one-sided differentiation is acquired, and is subject to progressive perfection throughout life. The machine is becoming more and more perfect. Dividing the machine in two parts of the brain is degradation, is against progress, and the inevitable differentiation of function. "Ambidexterity"-mongering is the most absurd silliness.

Note that there is no discoverable difference of microscopic structure between the corresponding unused brain-tissue on one side, and that in the cerebral speech-center much used on the other. And note again that the choice is open to the attention or will to elect in infancy either side to work from, and thus to make the individual either righthanded or lefthanded. Observe also that as about 96 per cent. of people now are righthanded, the supposed "laws of heredity" are put utterly out of court so far as pertains to the number of the lefthanded. Every lefthanded person must have had millions of righthanded ancestors for every one that was lefthanded.

Not to be omitted, too, is that with all the actual or possible education of the left cerebral center in the righthanded (or of the right in the lefthanded), there is a poorly cooperating observing or reversing, or mirroring mechanism of the other side which can be brought into use by the attention. The psyche is, therefore, again demonstrated to be something more than the mechanism. It plays at will upon the mechanism. It plays badly, if you please but the mechanism does not play itself! Attention is merely the name we give the metaphysical player; the cerebral engine cannot run itself, or the piano play itself any more than could the locomotive or the musical machine. In depriving one hand or one center of the attention, we make the other an automatic "trailer" (as I have called it), working by means of the commissural fibers between the two oppositely-placed centers, but working badly, largely without the sense of direction, form, topography, etc. The attention, therefore, adds all-important elements to the mechanism. Psychology can no longer ignore pathology, or aberrant physiology.

Now, what is this "Attention"? As before, the question can be answered only genetically. The brain comes out to see, but only succeeds in really seeing with some comparative degree of accuracy at about five or six months after birth. *And this is precisely the date at which righthandedness, or the reverse, appears.* In about 96 per cent. of infants the right eye is the better-seeing eye, and thus compels the right hand to work with it. Thus, vision is the father of action, of righthanded action, and righteyedness is bound up as a precedent, synchronous, and causal factor of righthandedness. The writing illustrations above given show that spacial relations are created and definitized by "ocular attention." Direction, location, measurement—all topographical factors, are thus products of vision. But a secondary product has been evolved, its working illustrated in the writing illustrations, which may be called psychic or mental attention. It is plainly a derivative or product of ocular attention because it can only exist separately when the visual attention is not upon a (usually) moving object. With the eye closed it may be brought into existence, but its derivative nature is again evidenced by its imperfection of work, the lack of direction, of accuracy of topographical qualities, etc. With the active vision renounced, it may even be turned upon sensations not visually derived, such as of sounds, odors, tastes, etc., but all sounds at least are topographical and directional; pain and touch are of the localized parts of the body, or again spacial in nature, and even taste is located in the mouth. The brain did not make out of its own substance the peripheral organs of hearing, taste, touch, etc.: the eye alone is brain-substance told off to a special mental and cerebral duty which was prevented by a nontransparent skull.

The execution of a compositely-formed resolve requiring first of all vision, then possibly other sensational stimuli, but always memory, *i.e.* the stored results of all previous coordinated activities, words, speech, etc., can issue in swift and decisive act only through the placing of all the most directly intermediating cerebral centers in the closest possible contiguity in one side of the brain. If one is righthanded his centers for writing, speech, and memory must be on the left side. Upon the same side, therefore, must be the visual and other centers which furnish the chief data for the compositely-formed act. If one or more important data must come from centers in the opposite half-brain, delay at least must ensue, and other doubts and inaccuracies also. Hence the all-necessary concentrations of the chief organs and functions in one side of the brain. The organist plays on several banks of keys, and with pedals, uses scores of stops, reads five staffs of music, etc., that is, he really plays on many organs at once. But his banks of keys and stops must not be located on different sides of the church, or even beyond the reach of his arms. The two cerebral cortical hemispheres are indeed somewhat connected by commis-

sural fibers, but poorly so at best, as our trailing handwriting shows. Biologically, the safety and success of the human organism has always depended upon the most intimate, accurate, and swift coordination of many factors and cortical centers in order to issue in resolve and action. Such coordination could not take place if the cortical centers furnishing the necessary data for action were divided equally between the two cerebral hemispheres.

The difficulty of understanding the nature and origin of mirror-writing has come from the fact of looking at it as the result first of a pathological state of mind or nerve action, and secondly as the work of a finished or completed mechanism. Pathology has nothing to do with the matter; it is physiological and natural, due to the action and degree of attention, and it is also a product of education, habit, or development. Soltmann, Erlenmeyer, Marinesco, Sollier, and others look upon it as a pathological, and as a finished and presented fact. Others, Buchwald, Durand, Vogt, Nicolle, and Halipré, Meige, Bernard, Ballet, Figuera, etc., hold it to be normal of the left hand in the righthanded, sometimes even in the lefthanded. In 77 deaf mutes Soltmann found 35 per cent. wrote mirror-style with the left, and he concludes that "the more educated the person the less he will fall into mirror-writing with the left hand." This is the reverse of the truth, and nothing is said as to the fundamental condition—the fact of precedent lefthandedness, either continued or overcome, and of mixed types.

A simple device would have put all such errors to rout and would have shown the truth. The difficulty in writing in the manner habitually chosen is forgotten; it is an art, slowly and laboriously acquired, and always poorly executed, this writing on a table or a flat surface in front, and with the body craned to the left to see with the right eye the writing which is being executed. (By the left eye in the lefthanded, of course.) And also there is a universal neglect of the direction in which the hand is commanded to write. If one writes mirror-style he must write towards the body with the right hand, and away from it with the left. This is demonstrated by the plan here proposed: Place the surface upon which the writing is to be done upright—a solidly fixed sheet of plate-glass is best—the edge at right angles to the face and almost against the nose and forehead; attach sheets of quadrille paper upon either side by clamps. Thus is avoided the great difficulties the imagination and eyes have in projecting outward the image or seeing the writing which is being executed. The skewed, indirect, absurd-angled, reversed, and illogical writing posture is avoided, and the upright sheet of glass is as if the two-sided mirror were placed between the two cerebral halves. The writer should be one innocent of all such experiments, *i.e.* not used to put his educated consciousness or attention through any "tricks" or tasks; a pencil should be in each hand, the points on the sides opposite to each other. Neither eye can now be used if the pencils are started within a few inches of the eyes, so that the eyes may be closed, and the experiments will be all the better for the free working of the attention on the surfaces directly in front of the eyes. Synchronous writing under these circumstances will, in the righthanded, always show normal style with the right hand, and mirror-style with the left—or the reverse in the case of the untampered-with lefthanded. Fix the attention of the righthanded upon his lefthand writing, and command it to write normal, and compel the right to make some movements; it will make attempts, at least, at mirror-style. The higher the expertness and mental culture the more certain will be such results. On the table before us vision, and that imagined vision we call central attention (with peripheral vision abrogated), controls or tries to control, but has so many difficulties that it has falsified and confused all experimentation. The left tries to write as does the right. My device removes confusing factors and conditions, and proves that everybody normally writes mirror-style with the trailing-hand, but dependent upon the all-controlling factor of the direction of the writing, and upon general education, imaginativeness, skill, habit, the development of central attention, etc. Sign-language, warfare, etc., first originated the habit of righteyedness and so of its resultant righthandedness, and this necessitated the location of the speech center in the left half-brain. The particular incidence, now, in a certain child, of righthandedness or lefthandedness, depends upon which is the better seeing eye, when arm-and-hand motion arise and are coordinated with the function of the precedent and governing eye. Heredity has nothing to do with the matter directly, and only indirectly, in making the right eye the better seeing eye in infancy, and when the habit is established. In about 96 per cent. the right is the better seeing eye. If it is desired to make a lefthanded babe normally righthanded, the process must be begun in the earliest stages, and by means of giving the right eye the better function. This may now be held impossible, although atropine in the left eye of the child with begining lefthandedness might possibly be efficacious. *Let no one attempt it!* Pathology follows almost inevitably any interference with Nature's institution of handedness, right or left, however early it may have begun. For the mixed type is far worse, and usually ends in more suffering than if lefthandedness were of the pure type.

In two-handed mirror-writing, and in the work of the trailing hand, there is more than a suggestive hint, there is an intimate glance permitted into the mechanics of the construction or connections of the two-sided brain. It also comes out in the often-described experiment of writing with one, and then with the other hand upon paper while looking at the figure being made in a mirror set at right angles vertically in front. In a righthanded person the making of a square or triangle with the dextral hand is possible and comparatively easy, but on attempting the same trick with the sinistral hand, without forethought and quickly, the direction will be ludicrously reversed. Now, synchronous two-handed writing, by the righthanded, is easier and more commonly possible if the left writes mirror-style and the other normal style. The commissural fibers, the pattern-making threads, between the two opposed cerebral mechanisms, let us say between the two patterned or figured cloths, seem therefore to run from the "face," or "right" side of one, to the "back," "wrong," or "seamy" side of the other. Changing the analogy to that of two mirrors, the face of the mirror on one side of the brain reflects and normalizes the figure of the obverse or back side of the mirror on the opposite side of the brain. The mirror or cloth erected in the left brain of the dextromanual fronts consciousness and its figures are normal, while that in the trailing side is mirror-writing, or is the "seamy," "wrong" side of the cloth. In reference to the eyes, besides the evident facts termed righteyedness and lefteyedness, one of an equal or greater importance comes into view, which I have called *dominance*. Usually and normally a righthanded person is righteyed, and a lefthanded one is lefteyed. That is, the right eye is normally the dominant one in the righthanded, and the left eye in the lefthanded. A simple test, one of

many, of dominancy, is easily made and thoroughly convincing. Hold the pencil or finger upright a foot from the eyes in the median line and observe the image it makes on the opposite wall; closing the left eye results in no movement of the image on the wall, but closing the right or dominant eye throws the left eye into hitherto disused or non-selected function, and the image "jumps" suddenly to the right. The demonstration of the dominancy of the right is thus apparent; the mind must not be confused in action by two differently-placed images, and has learned to ignore the one and rely upon the other. And it ignores the least reliable and least accurate or useful image, which is the left in the dextral. Correspondingly, of course, the choice is reversed in the lefthanded person. And it is as evident that a high degree of ametropia, squint, amblyopia, or other disease, of the naturally dominant eye, would transfer the dominancy to the eye of the other side. In such cases the mind and entire organism is morbidized, decision and action are confused, delayed or inhibited reflexes are necessitated, stuttering and halting speech or thought appears, etc. This is because the right eye of the four-footed animalian phylum has controlled the motion and placing of the right front foot, guarded the right side of the body, etc., and primarily established the great law that cooperating cerebral centers must be in the same cerebral hemisphere to render decision and action the most exact and quick. Contiguity of these centers insures accuracy and celerity, while the location of one or more centers in the opposite hemisphere demands the intermediation of commissural nerves between the two halves, with which pathology arises. These morbid results are painfully evident in the sudden loss in adult life, of the dominant eye, or the more expert hand. To the observant they are equally evident in those naturally and healthily lefthanded persons made morbid by the morbid "ambidexterity" sillies. These persons put Nature to the foolish task of creating a second set of subdominant or equidominant cerebral centers where, according to God and common sense, one was not only sufficient, but infinitely better. In such cases the dominancy of one eye is done away with and an equidominance or alternate dominance is established. Two images of the pencil on the wall are seen, and neither is unconsciously to be ignored.

Almost the sole method and means by which we come into large and intellectual relations with the world are the results of vision. The total contributions of all the other senses compose but a fractional part of the ocular ones. Intellect itself is little more than epitomized ancestral visual experience. Nearly all our thinking is in images, pictures of things seen, and even the most scientific, even the most abstract and metaphysical intellectual processes are only seemingly amorphous; they are really like the crystalline coal-measures of ancestral and personal visual experiences. The difficulty is to draw the line between the inherited and the individual parts. The *"tabula rasa"* of the infant mind is by no means blank, but its inheritances are necessarily abstract, and are vivified and definitized by the daily millionfold personal, *i.e.* chiefly retinal, images poured among the ancestral carbon strata awaiting the touch of reality to awaken them to living light and heat. A truer analogy presents in language the fused and packed epitome and record, the composite photograph, in fact, of racial experience. Nearer far to his personality than any other or all other products of Man's being here, the most immaterial, most spiritual record of his existence, is his language. And languages are almost wholly the records of things seen. The greatest deed of mankind is the creation of the alphabet; so arduous was it in fact that only one alphabet has been evolved in and for the whole world. All are at one in the conclusion that this alphabet is the *sine qua non* of intellectual development and of the condition we call civilization. Well, the alphabet, as all know, is made up of the conventionalized pictures, ideographs, eye-made images and photographs of objective scenes and things. The seeing of things correctly is the foundation and condition of knowing things rightly and truly—*i.e.* of civilized living and scientific thinking. Conversely, the seeing things badly and distortedly, *i.e.* ametropically and with optic morbidity, is the source to-day of more suffering and improper living than all other pathogenetic factors combined. In all past time the composite of millions of ancestral visual experiences have been forming what we call mind, intellect, and memory. The elimination of the visually unfit has made the present-day heir of all the ages the product of predominatingly and relatively perfect eyes. Civilization adds an amazing acuteness to the present tragedy when an ametropic organism comes in bitterest personal clash with the inherited datum of all past experience. "Eyestrain" is thus usually the greatest misfortune which can happen to a civilized "near-worker." It morbidizes mind and body and is wrecking numberless lives all about us. Some day medicine will be aroused to the amazing reach of this awful truth, and in that day medicine, and especially psychiatry and neuropathology, will be revolutionized.

One may go further and say that not only is human life and civilization itself the quintessence of summarized visual experience, but the very development and evolution of biological forms above the lowest has been dependent upon vision. *Ubi motus ibi visus est* is the key of most higher organic evolution. Food and defense have always depended upon vision and perfection of vision, and the development of more perfect vision has been the forerunning means of the production of more perfect forms. The Darwinian exclusion of the unfit has been largely the exclusion of the visually unfit, and the survival of the fittest has been the survival of those possessing the best ocular mechanism. No task in organofaction has been so difficult of achievement and of healthy preservation as that of making the most perfect ocular mechanism.

One of the most inscrutable and important powers of the psyche is attention, but is it not almost entirely a product of visual function? In the congenitally blind and exaggeratedly ametropic the same truth comes to clearness. The inherited or epitomized experiences of the ancestry have operated in them, and in all of us, to beget the secondary and acquired kind of attention which we have in varying degree, and which may be called mental, intellectual, or central—that coming to view with deprivation of visual attention. It is inaccurate and imperfect, especially topographically, as our illustrations, even from a highly cultivated mind, show. The fundamental distinction has not been emphasized that visual attention depends largely and chiefly upon the following of the objectively moving thing with the eyes, or what amounts to the same thing, upon movements of the eyes to reestablish sensitiveness of the retina. Absolutely persistent gazing at an immovable point quickly results in inability to see it. The moving object rivets the attention, and so long as it is visually fixed mental or central attention and visual attention are fused into unity. There is no possibility, except possibly by training, of attentively observing a moving thing like the pen-point or the letters being made by it, while at the

same time mutually and continuously attentive to another train of thought, memory, or objective happening. The bimanual writer may write the same letters and words synchronously, but not different words. This is simply because the eye cannot see different words being written. As all students have agreed, consciousness or attention is like a simple stream of sand passing through the constricted part of the hour-glass. The attention of an expert organ player, playing with feet, two hands, pulling stops, reading several lines of notes, varying the expression, etc., each second, seems almost to contradict the validity of the hour-glass comparison. It appears to be a widely spread-out rain of attention, different from the more primitive and naive or hour-glass kind of the rest of us. But even this is due, I believe, to an acquired ability of perceiving and acting upon the perimacular and more peripherally placed images of the retina. Most of us actually use and attend to the macular image, and the retina beyond is used only to call the attention of the eyes to an object not really or perfectly visualized and perceived, but which by ocular motion is at once brought upon the macula and then clearly perceived. Watching an organ-player read and play new music shows one that he has a staring and indefinite expression, which argues a large field of vision and attention, filled with many objects, all held in a synchronous, graded, and differing clearness of attention, impossible to do except after long education and practice. And this extension of visual attention to the images of the notes, keys, etc., located farther and farther beyond the macula, requires that they shall be visually and essentially correlated. The broadening of attention to multiple objects, the holding in synchronous unity seemingly discrete streams of objects and influences, seems, therefore, a matter of education, not of primary endowment, of progressive development and widening, instead of abrogation of the single-current, and depends primarily and wholly upon the ocular extension of the synchronous recognizability of correlated images falling farther than usual beyond the macula.

The visual central (or mental) attention is separable from the peripheral visual attention only when peripheral visual attention is abrogated. That this central attention is derived from the visual is its pale, possibly ludicrously, inexact reflex, is apparent, even without the striking demonstrations shown in the writing illustrations given herewith. It is essentially of the nature of a *pis aller*, reminding one of the pathetic almost incoherent falsetto of the acquired speech of the deaf mute. By long cultivation it gains precision in the mind of the orator, musician, etc., but the extramacular education of the retinas lies at the foundation of the proficiency.

The origin of right-handedness and lefthandedness I have elsewhere set forth in detail, but must here epitomize. There is no reason to suspect even the most vague or far-away beginnings in animals. So long as the four feet are used for locomotion there could be no lateral differentiation of function. I have watched for it in squirrels that use their front paws to hold nuts, cats that strike at insects in the air, or play with wounded mice, and in many other animals, but I am sure that to neither paw is preference assigned. There is thus probably no dominancy of either eye in animals. Even in the monkeys and gorillas, who of all animals most use the forepaws as hands, one catches no suggestion of preferential use or superior expertness in the dextral or sinistral side. (My very intelligent dog, trained to "shake hand" with his right paw, lost his right eye, and after that he always offered the left paw.) But in the lowest human savages all over the world choice or greater expertness of one hand is as clearly present as in civilized races. No savages, however, are so near animalian conditions as to exhibit its differentiating origins. Fixed in all our military and social customs, and living at the base of language itself are two facts which solve the riddle and make clear whence and how right-handedness arose. In all tribes and countries since man used implements of offense and defence, the sinistral or cardiac side was protected by the shield and the sinistral hand was called the shield-hand, as the dextral was called the spear-hand. Next to fighting and synchronous with it was the need of barter, and the fundamental condition of bartering was counting with the low numbers, one to ten. The fingers of the free or dextral hand were of course first used, and all fingers are to-day called digits, as are the figures themselves, and the basis of our numberings is the decimal or ten-fingered system. The tally-stick, notched or numbered, is the record of the digits held in the air. Every drill and action of the soldier from Xenophon to West Point is dextral in every detail. The dominancy of the right eye is shown in firing from the right shoulder and sighting with the right eye. I have two patients, lefthanded in every respect, who have been taught to fire their guns from the right shoulder; but of course they are lefteyed, and they depress the right eye below the level of the gun, and sight with the dominant left eye. Rightfootedness, less differentiated of course, must follow righthandedness and righteyedness, so that all soldiers (and free masons, too) must step off with the left foot first, *i.e.* the spring must be made with the right. The loss of the right hand, or right eye, mutilations, etc., very common in barbaric times, would help to account for the preservation of the present four per cent. of lefthanded people.

Because the underlying and governing condition why the man must be generally dextral, or generally sinistral, is the evident necessity that the centers governing a coordinated set of functions, must be located in the same cerebral hemisphere. To make any important act precise, purposive, harmoniously, and rapidly effective, several interacting and fusing cerebral centers must conjoin their functions: Vision, the chief of all, must present the problem, determine the spacial or topographical relations, etc.; hearing, smell, taxis, etc., may or may not enter into the matter as auxiliaries; memory of past facts, stored chiefly in the same side of the brain, undoubtedly is called upon for other data (and memory is almost entirely a gallery of stored photographs made by the eye!)—then judgment and decision, working upon the data gathered from all subordinates, issues in the word which is the seal of volition, and in act which is reality or the incorporation of the psyche in objective sense and effect, in the materiality, beyond cancellation or change. The essence of the matter is, therefore, were the chief of the contributing centers creating word and act divided between the two cerebral hemispheres, the certainty and celerity of the word and act would be lessened by the difficulty and delay consequent upon fusing the products of these remotely placed and poorly united centers. Hence the law that the better expertness of the chief dextral organs requires that the other cooperating organs, also more expert, must also be upon the dextral side. And *vice versa* of sinistral expertness. The centers of all organs contributing to the composite terminal act must be in the same cerebral hemisphere. All physiology and pathology show that the speech center, a single organ, can be and is located in only one side of the brain, sinistrocerebral in the righthanded,

and that the hand which executes the writing act, the most intellectual of all acts, dominates the location of the speech center in the opposite half-brain. The "ambidextral" societies, the mothers and school teachers, who would martyrize children naturally lefthanded by compelling them to learn an equal expertness of the right hand, are the most blunderful of stupid persons. No person ever was or ever can be made equally expert with both hands, and every attempt results in tragedy for the patient. To carry out the egregious plan thoroughly, flutes, half the violins, carpenters' and mechanics' tools, etc., and half the pianos should be made for the dextral "ambidextralists," and half for the sinistral "ambidextralists." All musicians should play half the time lefthanded and half righthanded on reversed piano keyboards, reversely strung violins, etc.; all carpenters and mechanics should work one day righthanded and the next lefthanded, with suitable tools; all soldiers drill lefthanded and leftfooted one day, and the reverse the ensuing day, etc., etc. What a world it would be if those who are wiser than God and Nature had their way!

Were it so, all laws and customs as to the "Rule of the Road" would have to be changed so that carriages, foot-passengers, etc., should pass half the time to the left and half to the right. All double-track railroads would then order trains to pass one day to the right and the next to the left, and their locomotive engineers would then sit half the time on the right side of their cabs, and the other half on the left side. It took a whole generation time of experiments and mechanics to learn that the engineer must stand or sit on the right side of his engine or cab in order that he could look ahead with his right or dominant eye only, and without sticking his entire head out, as he would have to do if he sat or stood on the left side. The railroad men never learned why this is so, do not know why to-day, and to make the desirable change in two American left-passing double-track railroads, while it would finally avoid expense and accidents, would cost at once many millions of dollars. Thousands of years ago knights and men fighting on foot or horseback had to approach and pass each other on the left in order to strike or spear each other with the right hand while the shield-hand held the shield or the reins. The railway engineer, civil or locomotive, does not know that the knight was his right-handed and righteyed progenitor and endower.

A flood of light is thrown upon history, sociology, and medicine, especially upon psychology, neurology, and psychiatry, by lefthandedness and its sequels. Of every million born at least 30,000, probably more, are naturally lefthanded, so that in the United States there are nearly 3,000,000, and in the world over 45,000,000, thus handicapped. An indefinite proportion of these have been, or are being doubly cursed by the efforts of the foolish parent or teachers to make them righthanded. Sad suggestions and illustrations of the baleful results of the work of these improvers of Nature exist in such simple facts as that *right*, which should mean only dextral or righthanded, has come to mean good, moral, advisable; and *left*, or sinistral, has become sinister, awkward, unlucky, to be avoided, both person and thing. *Dexterity* and *dextrousness*, properly meaning only *dextrality*, have become synonymous with expertness and exceptional proficiency, whereas everybody knows that the lefthanded person, if purely so, is as cunning of hand as the righthanded. Even the superstition of the "evil eye"—the nondominant one—teaches the same lesson. In all ages, and now surely, there are everywhere strange and unaccountable cases of "failure in life," "peculiar," "odd," "awkward' folk, cranks of a hundred types, misfits, stutterers, and all that. What a light the misplacement of the cerebral center for speech and writing, or its pernicious double placing and maleducation and crippling by "ambidextralists," throws upon the origin and fate of many stutterers, and upon many of the "hopelessly stupid," the laggards in school! How many of the medieval court jesters and the derided, the town-fools, the kyphotics, and cripples were the products of the "sinister" superstition of the righthanded tyrants? And how many of the morbid-minded and insane?

Incidental and accidental results of the study of these cases would solve many problems and mysteries of medicine, and surely of psychology. Pathology is physiology gone astray. The thoroughgoing study of individual cases of aberrant neurology will be found to illumine many of the dark places of mental and moral genesis, function, and law.

ACUTE ANTERIOR POLIOMYELITIS, OR ACUTE SPINAL PARALYSIS OF CHILDREN;

REMARKS ON THE EPIDEMIC NOW PREVAILING IN NEW YORK.

By JOSEPH COLLINS, M.D.,

NEW YORK.

PROFESSOR OF NERVOUS DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; PHYSICIAN TO THE CITY HOSPITAL; NEUROLOGIST TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

ACUTE inflammation of the gray matter constituting the anterior horns of the spinal cord, and resulting injury of the ganglion cells, from which spring the motor nerves of the body, acute anterior poliomyelitis, as it is commonly called, is a disease around which much interest now centers. First, because it is prevailing epidemically in New York and its environment; second, because we are still entirely ignorant of its real causation and mode of propagation; and, third, because it is the most pitiable disease that exists. Vigorous, lusty young children sicken abruptly with what seems to be a comparatively trivial disorder, which is over in a few hours or days, but which leaves the child a hopelessly maimed, paralyzed wreck. As a small, innocent-looking cloud that appears above the horizon of what seems a perfect summer day, may be the initiative of a tornado which injures, wrecks, or destroys every object of man and Nature within a very narrow precinct, leaving those immediately adjacent unharmed, so this dreadful disease takes its course, while they who devote their lives to safeguarding the sick stand by, impotently, like firemen without water at a conflagration that is consuming priceless treasure.

Inflammation of the gray matter of the spinal cord has been recognized as a distinct disease since 1855. It was about that time that Duchenne of Boulogne began to subject the diseases of the nervous system to the searching investigation that entitles him to be considered the first really great worker in the field of clinical neurology. Naturally, the disease had often been described in the century preceding Duchenne's advent, but none of them was fundamental. For instance, Underwood, in 1784, called it dental paralysis, to convey the idea that it was dependent upon teething. The work of French investigators from 1860 to 1870 soon put the disease upon a firm anatomical basis. Slowly and laboriously its clinical features and course have been established, while little progress has been made with the causation of the

disease. Until its cause is discovered, we can make no headway in stamping it out. After the advent of the bacterial origin of acute disease, and particularly after it was demonstrated that other diseases of a similar course were due to specific organisms, it naturally occurred to many that this disease might be thus dependent. The most important contribution to this view was furnished by the prevalence of the disease in epidemic fashion and in several members of one family. The principal epidemics that have prevailed lately are those that have been reported by Medin of Stockholm (Vol. II., Tenth International Congress at Berlin); Caverly of Vermont (*Journal of the American Medical Association,* January, 1896), and others to be mentioned.

The earliest report of a group of cases is 1843. Colmer says in the *American Journal of the Medical Sciences,* 1843, that he saw six cases in 1841, and that the parents of the children reported eight to ten cases all occurring within an area of a few miles. Bergenholtz in Umea in 1881 reported a small epidemic of thirteen cases in rather a short time.

Cordier reported thirteen cases near Lyons during June and July of 1885, with four deaths. But the epidemic reported by Medlin was the first important one. It began in May, 1887. In that month there were four cases, in June one case, in July two cases, all typical. In August it began to take on the character of an epidemic. Two cases occurred in the same family, one of which ended fatally. There were three deaths among forty-four cases. In two instances two children in the same family were stricken. The cases were mostly among the working class. No unusual climatic disturbances prevailed. Constipation was noticed in the majority of the cases. Somnolence in the acute stage was very characteristic; at times it became a deep stupor. In a few cases there was a five to six-day remission, followed by return of fever and extension of paralysis. A few patients completely recovered. Since then epidemic have been reported in Norway by Looft (*Med. Revue,* 1900) and Leegard (*Norsk Mag. for Laegeridens Laben,* 1901).

Dr. D. H. Mackenzie of Mabbettsville, New York, reported in the MEDICAL RECORD, October 4, 1902, a small epidemic that occurred in Dutchess County, New York, in 1899. There were about thirty cases confined to an area of country about ten miles in diameter. Adults were attacked as well as children.

R. B. Wade of Stanmore, Sidney (*Australasian Medical Gazette,* July 20, 1904), mentions a report of an epidemic by Altman of South Australia in March and April of 1895.

Wade's cases occurred in the summer, *i.e.* in December and January of 1903-4, although not the hottest months. There were 34 cases—16 males, 18 females; youngest 13 months, oldest 7 years. There was nothing very striking in the symptomatology, save the very mild fever. The temperature varied from 100° to 102°, and the most marked symptom was pain along the affected limb. There were two cases with complete recovery.

Litchfield, another physician of Sidney (*loc. cit.*), had 25 cases, as follows: December, 1903, 9 cases; January, 1904, 12 cases; February, 1904, 2 cases; March, 1904, 1 case. He notes that the summer was wetter and cooler than usual. There had been during 1903 an extensive epidemic of gastrointestinal influenza, so that all through the summer pertussis was rife, and there was the usual crop of enteritis, but he could trace no direct connection between them. He does not mention deaths. The epidemic reported by Caverly began early in the summer of 1894 and lasted until October 1. The summer was unusually hot and dry. He reports 132 cases, of which 55 occurred in Rutland, which was also the starting point. Drainage did not seem to influence the spread of the disease. The water supply was also excluded as an etiological factor. Absence of history of infectious disease was mentioned as an etiological factor. It preponderated among strong, healthy children. Thus, of 46 cases, it was noted 35 times in children of good health and 11 among children in poor health. Eighteen deaths occurred.

The present epidemic in New York and its environment began apparently in early August of this year. Its extent and prevalence may, in a measure, be estimated from the records of the Hospital for the Ruptured and Crippled, to whose outdoor department come more cases of poliomyelitis each year than to all of the other institutions in New York. In 1906 (*i.e.* from October 1, 1905, to September 30, 1906, that being the Hospital year) there were 379 cases diagnosticated as anterior poliomyelitis and infantile paralysis, while in 1907, for a corresponding period of time, there were 550 such diagnoses. This was distributed in 1907 as follows:

	Anterior Poliomyelitis
October, 1906	44 cases
November, "	27 "
December, "	16 "
January, 1907	19 "
February, "	18 "
March, "	25 "
April, "	26 "
May, "	21 "
June, "	27 "
July, "	55 "
August, "	116 "
September, "	156 "
	550 cases
October 1–15, 1907	57 "
	607 cases

Thus it will be seen from an examination of this table that there was a striking accession of cases in the last two months of the year, 272 patients with poliomyelitis, *i.e.* nearly half of all the cases of the year came in August and September. Now, of these 550 cases, a certain number of those which were labeled infantile paralysis are not cases of anterior poliomyelitis, but cases of polyneuritis, especially post-diphtheritic; cerebrospinal meningitis; a few are cases of transverse myelitis and of pressure palsy, while others are cases of cerebral lesion. I have no positive data, but I should think that about 25 per cent. were of such a nature. That would leave about 200 or more cases of poliomyelitis, in the months of August and September of this year, which I believe to be about the correct number. In my own department, to which the patients coming to the hospital go on Mondays, Wednesdays, and Fridays, probably there have been since August upward of 150, all of which have been examined by myself or by my assistant, Dr. Theodore H. Romeiser. There are no means of finding out how many cases have existed in New York, but I think it is safe to infer that not more than one-quarter of all the cases that have occurred in New York have sought relief at the Hospital for Ruptured and Crippled. This would show that there have been upward of 1,000 cases. It is not forgotten that some of the cases that go to the Hospital for Ruptured and Crippled go also to other outdoor clinics, but we have taken particular pains to inquire of each parent whether or not they have been with their children to other clinics, and it is very uncommon to find that they have. For instance, at my clinic at the Post-Graduate Medical School, where we have had thirty-five cases since July, none of them have been enrolled as patients at

the Hospital for Ruptured and Crippled. Another very interesting matter to determine at the present time is, is the epidemic on the wane? From our statistics it may be said that it is, although 57 new patients sought relief during the first half of October; but many of them are patients that sickened in August and September.

The remarks that I shall make concerning the etiology and symptomatology of the disease are based upon cases that have been seen in my own clinics and in private practice. Practically no new light has so far been thrown upon the etiology of the disease, save that it does not seem to have had anything to do with the causes that are commonly mentioned in the books as predisposing or accessory causes, such as fatigue, hot and sultry weather, and digestive disturbances. As a matter of fact, as everyone knows, this summer has been a cool one, and in New York an extremely dry one. In a very small number (14) of our cases there was a history of marked digestive disturbances, and by that I mean diarrhea, vomiting, and the ordinary accompaniments of stomachic and intestinal indigestion. Nor have I been able to make out that the occurrence of acute poliomyelitis stands in any relationship to defective sanitary surroundings. In every case an effort has been made to inquire into this, and in most instances successfully. No special district of the city has been selected for the prevalence of the disease; they have come from all over the tenement-house districts, from which of course the majority of our dispensary patients come, and from practically all adjacent environs. In four instances more than one member of the family have been affected; in one instance three children, in the other three, two children. In the family of which three were afflicted two of the children had it simultaneously; the other about a month later. One of these children recovered completely; one has only slight paralysis and slighter atrophy of the left shoulder girdle, and one has dangle legs.

The following table shows that the dangerous age is from one year to three years. In this epidemic there have been very few patients beyond four years.

It was a striking fact that the majority of the children were in good health when they were seized by the poliomyelitis.

The symptoms of anterior poliomyelitis are, as is well known, sharply defined. A young child in good health becomes peevish, restless, irritable, and displays manifestations of pain and discomfort on being handled, and soon develops fever, which is sometimes accompanied by vomiting and occasionally diarrhea. These symptoms continue for from two days to a fortnight, the average period being from three to four days. The mild fever, 101° to 102°, the peevishness, restlessness, and irritability, or torpidity, the obvious great discomfort on being handled, being the principal features. In a few cases meningeal symptoms are conspicuous. Then the fever disappears, the child becomes quiet, bright, and alert; oftentimes it is even playful and attempts to get up. Then it is found that it is paralyzed in one or more extremities, oftener in the legs than in the arms, but very often in both legs and both arms, or one leg and one arm. After a week or two the paralysis begins to disappear in one or more of the limbs, and at the end of a few weeks it is often limited to one extremity, or a part of one extremity, to a group of muscles, or, in very rare instances to one or two muscles. During this time, which is consonant with the disappearance of the œdema around the inflammatory area in the interior gray matter of the spinal cord, the paralysis is clearing up.

The epidemic of the disease now prevailing has not so far added to our knowledge of the causation of the disease, but it has materially contributed to our knowledge of its clinical history.

The atrophy of the muscles that develops is in keeping with the intensity of the process in the ganglion cells of the anterior horns by the inflammatory area out of commission. When the cell bodies of the nerves going to these muscles are destroyed or seriously damaged, atrophy sets in. From that time on the symptoms, aside from trophic manifestations, are deformity induced by the atrophy of the diseased muscles, and unopposed manifestation of tonus in the unparalyzed antagonistic muscles. The inflammatory process may be at any level in the spinal cord, oftenest in the lumbar region, next in the cervical, rarest in the oblongata and pons. The paralysis and atrophy bespeaks accurately the location of the inflammatory process, but in the beginning of the disease, *i.e.* during the febrile period,

there is no way of telling what level of the cord is going to be the focus of the disease.

The noteworthy symptomatic feature of the present epidemic is the considerable percentage of cases which make a fairly good recovery, *i.e.* a recovery without marked atrophy, and in this respect I think the epidemic now prevalent differs from what has heretofore been described. In marked contradistinction to this is the relatively large number of cases in which the oblongata and the pons have been the seat of the lesion. Naturally, the majority of such cases do not come to the dispensary, because they succumb in a comparatively short time after the occurrence of the disease.

First, as to the cases that terminate in recovery. In all the epidemics, so far as I have examined the literature, there have been recorded recoveries, but they are very few, and the idea of complete recovery from what seems to be a genuine, fully developed case of anterior poliomyelitis, was to me quite novel. It is too early to give statistics of the cases that have recovered. Many of them are still under observation. Some of them will not eventuate in complete recovery. We consider a case recovered that does not exhibit muscular atrophy. The kind of cases that we are seeing in our clinics have a history somewhat as follows: The child sickens with the ordinary symptoms of the disease, and in customary way develops paralysis of one or more extremities. After two or three weeks, in some instances a shorter period, the child begins to move the paralyzed members, and the recovery progresses until he is able to use them all, save perhaps one or more groups of muscles. So far the occurrences are as they are related in the books. But in the cases of which I speak the groups of muscles which have not up to this time regained their function, do not begin to atrophy, as they do in the ordinary case; they gradually regain their function. This point is well illustrated by a child of three years, who, four weeks after the acute phenomena of the disease had subsided, had a weak, wobbly, right lower extremity and flaccid dangle-leg state of the left. Orthopedic apparatus was ordered to maintain the legs in a position that would militate against deformity, but when the apparatus was ready the child was able to stand and to walk, not as well as it could before the illness, but it has gone on getting better steadily, until now it is quite well. We have had several such cases, some in the hospital under constant observation. The explanation of them is that the inflammation in the anterior horns is not so intense as to destroy the cell bodies and nutritive processes of the peripheral motor neurons. The inflammation and the resulting edema puts these neurons out of commission for what seems a very long time, but their structural integrity must be fairly well preserved, and as the edema and the other accompaniments of the antecedent inflammation subside the cells gradually take up their function. Some cells are undoubtedly destroyed, and there is a corresponding muscle fiber atrophy, but either a small number of cells are destroyed or the destruction is only partial, sufficient vitality remaining to maintain the nutrition, but not the tonus of the muscle. In these cases the knee jerks are generally absent or extremely sluggish, and this reflex comes back tardily.

The occurrence of such cases as these does not necessarily mean that the epidemic is a mild one. The epidemic that is prevailing now cannot be said to be a mild one, because there have been so many cases with bulbar and pontine symptoms, yet the disease, meaning the inflammatory process in this epidemic, is mild, rather than severe. I mean to say that even a mild inflammation of the anterior gray substance of the pons-oblongata is a most serious matter. The statistics showing the frequency with which this part of the cerebrospinal axis has been involved are not ready, but I may say that during the past month at the Hospital for Ruptured and Crippled, I have seen three patients with involvement of the facial, and with ocular palsies (abducens and motoroculus) and one with hypoglossal and vagus involvement. It is intended to present an analysis of all these cases later.

My only reason for publishing this preliminary discussion of the subject is particularly to call attention to the fact that physicians who are called to see these patients during the first two or three days of the illness have an unusual opportunity to assist in the discovery of the causation of a terrible malady, as well as to establish the truth about its symptomatology and prognosis. The diagnosis during the first three or four days cannot be made; it can only be suspected. And at this time, every child that sickens with symptoms that are known to be premonitory and early symptoms of anterior poliomyelitis should be treated as if they were genuine examples of the disease; that is, a lumbar puncture should be done, and the urine and feces collected, and in the investigation and interpretation of the matter collected the services of some Research Institution should be sought. If every physician who sees one of these cases in the beginning of the disease would do this, there would be some chance of determining its cause, a chance that is extremely minimized if investigations are begun only after the patient has been ill for a week. Meanwhile, it is of no service to speculate as to whether the disease is an intoxication or an infection, whether it is due to an organism that at one time causes meningitis, at another poliomyelitis. We know that the disease exists, that it is a most ghastly disease, and that the occasion is a favorable one to find out something about it; but, in order to do that, physicians practising among the persons in whom it is prevalent should be implored to seek the cooperation of those who, by training and skill, are fitted to investigate it.

37 West Fifty-fourth Street.

MENTAL DEFECTIVES; AN ATTEMPT TO TREAT SOME CASES WITH MEDICINES.*

By SIEGFRIED BLOCK, M.D.,
BROOKLYN, NEW YORK.

Few are the medical periodicals which have not at some time had an article concerning the lack of attention given by the medical profession to the study and treatment of beginning psychoses, especially as evidenced in a backward child, a moral imbecile, or one with some other slight mental deviation from the accepted normal standard. Instigated by reading these again and again, I made it my duty to look into the matter more closely. I have personally interviewed several of the most eminent neurologists and, with few exceptions, find they corroborate the statements of the journals. All of them agree that a great deal is being done for these conditions by able persons from a pedagogical standpoint, but the medical man is doing little from the physician's point of view. Many of the leager cities have in the public schools ungraded classes for those children who cannot keep up with the majority of the same age. Here, by schemes many of which are ingenious and highly creditable, the backward child is taught, and after untiring effort, at times some improvement is made. Frequently the children of the wealthier classes are under the personal supervision of a tutor or are

*For many of these cases I must thank Miss Grasse of the Children's Probation Society.

sent to a special school where the fault is to be corrected. In the Children's Court we hear daily of cases where a medical authority would not hesitate to diagnose the case of the prisoner as some mental disease made manifest by an act of immorality; yet this kind of child is often sentenced to a home or prison to keep him out of mischief. In all such cases, where does the doctor come in? Are these children not medical patients? Are they sick or are they not?

A well-known neurologist has written to me as follows: "Our institutions in this city, as in many other lines, do not see the beginnings of the disorders which come to them and neither are they properly familiar with the fields of knowledge that should be most useful to them (in fact, the whole present system of care and training, from the time of the elder Sequin, starts, goes, and stops from the pedagogical and not from the medical side)." The letter goes on to say, " a scientific rather than an old-woman etiology, is greatly needed." The *American Monthly Review of Reviews* for April states on the authority of the City Superintendent of Schools, that 40 per cent. of the children of the schools of New York are below the grades in which they should be, and 2 per cent. of all the children thus far examined are mentally deficient. There are ever so many more reliable reports of the situation, but, in order to shorten this paper, these two must suffice to show the gravity of the matter. About 75 per cent. of the school children have some such physical defects as adenoid growths in the throat, poor teeth, or faulty vision, hearing, or speech. With these corrected, much toward the betterment of the conditions will be accomplished. A more difficult condition, but one that may be alleviated by proper persons, is the result of improper home surroundings of the child, such as either insufficient or improper food, and what is still worse, criminal, drunken, or poverty-stricken parents. It is self-evident that such extraneous causes must be removed if possible, as is done in treating every other illness. It is, indeed, very rare to expect a boy to grow up into good, wholesome manhood with his home a veritable hell and his parents acting the rôle of his Satanic Majesty!

In quite a number of children I have found anemia, tuberculosis, or endocarditis, causing a physical defect which when improved materially aided not only the power of the mind in school work but also the moral behavior.

There is another class of cases. These have apparently a sound body with everything at home conducive to health, but the child at thirteen or fourteen years has no more wisdom or reasoning power than the normal child of seven or eight years. In this class are the dullard in school, with private tutors at home, the truant son of a good father and mother, the runaway, the kleptomaniac, the mischievous or stubborn boy who will never do what he is told, etc. These are the kind of cases that often need, to my mind, *medical* attention as well as a case of typhoid fever or pneumonia. How to treat these cases is the question that we as members of our profession have to solve. Prevent the progress of disease if it be a disease, prevent mental deterioration if possible. In some cases, at least, we may succeed. We may be able to save the bad boy from a life of crime, followed by a prison existence. We may be able, also, to keep a good many people out of insane asylums, etc. Just as in tuberculosis, if the incipient stage is properly treated, the final stages, of softening and cavities, may never come.

I do not claim that every case of mental disease is amenable to treatment. As is well known, a gross anatomical lesion as a spicule of bone, a tumor, faulty innervation, or even absence of some portion of the brain, etc., may be responsible for the symptoms. These can be no more removed by medicine than can an amputated extremity be restored by drugs. As Dr. Barr states in his work on Mental Defectives: "To replace what has never been placed is impossible." In speaking of the feebly gifted or backward child, the same writer goes on to say: "The feebly gifted or backward child has not crossed the border—he is not a mental defective but a mental invalid, so to speak, possessed of all his powers, and has the same chance of attaining mental vigor that any sickly child has of being brought to full health through proper treatment."

In cases of scorbutus we find citric acid (orange juice), a change in the diet, and improvement of the hygiene the three cardinal points of the most accepted method of treatment. The principal signs of this disease are a multitude of subcutaneous hemorrhages associated with anemia, lowered vitality, irritability, tenderness of joints, etc. We consider this disease as constitutional with symptoms quite generally present over scattered portions of the body; especially can they be found in the thinner and more delicate tissues, such as the mucous membranes, often also in the dense periosteum, etc.

Granting this fact to be true, I candidly believe, after examining quite a large number of cases of the so-called mentally defective and feeble-minded children, that the brain membranes, which are more delicate than the mucous membranes and certainly than the periosteum, are also subject to these ecchymoses. In fact, in about 10 per cent. of the cases among the better classes, I have been able to arrive at a history of scurvy, hemophilia, tuberculosis, or syphilis. In another 10 per cent. I have noted remarks such as "he has always been a weak child"; "he used to suffer with headaches," etc., then some of the symptoms that would intimate possible cerebral hemorrhages would be mentioned. In a few of these cases, the cerebral condition being only partially cured, it is possible to conceive that traces of pinpoint hemorrhages may be left in the meninges. These may be too small to cause localized pressure symptoms, yet large enough to produce either general mental dulling or irritation. Moreover, a good many of these spots may occur and be so diffusely scattered that an examination of a score of sections, cut as thin as is necessary for microscopical examination, may never show one of the minute partially absorbed hemorrhagic points.

Sudden dilatation of the cerebral vessels, as in some forms of excitement, be it grief or pleasure, may cause a new ecchymotic crop. Hence often, as in a few cases accompanied by epileptic fits, or so-called hysterical or maniacal outbursts, the result is made manifest after a time. With rest, good food, and good hygiene some disappear and some are left to become organized and form cicatricial contractures, perhaps very small, yet large enough to be a constant menace to the mind. From this theory we form an idea how many of the progressively increasing mental disorders may result.

In another class of cases where scorbutus has never existed, I believe it is possible to imagine that such pinpoint hemorrhages may occur in the brain and nowhere else. Of course, there are those cases of mentally defective children where the functions that are at fault never existed, such as the two kinds of moral defectives: the *unmoral*, or the child who never was taught what it is to be moral, and the *immoral*, who will do that which he knows is not moral.

The treatment in the first case is to teach the child, and if he accepts the teaching, he will be cured. The

other child is very different; he may be a mental invalid who is unable to appreciate as morality what the rest of the community in which he lives demands of him. In other matters, he may be exceedingly bright.

Case I.—I have a case in mind of a boy of 16 who runs away from his home every few weeks. He is dishonest and has been arrested dozens of times for all kinds of miscreancy. More than once he has said to me, "Doctor, I don't think you can do anything with me. I'm no good; that's all there is to it." This same boy is an excellent portrait sketcher, a fair violinist, a regular "pool-shark," a first-class swimmer, and a good baseball player. His home surroundings are very good. He is the eldest son of a wealthy and highly educated family. He has three elder sisters and one brother, all of whom are normal. I have had this boy under my care for some time. So-called "goody goody" talk was just as useless as threats of corporal punishment; in fact, after a thrashing he would act still more stubbornly. Four months ago I began to treat him as follows: I gave him saturated solutions of citric and nitric acids, and he was ordered to take one drop of each in a glass full of water three times a day. I increased each dose one drop daily until he was taking 10 drops three times a day. After one week his stomach revolted. I had to return to five drops per dose. This I had to reduce to three drops of each, which dose he is still taking. Since he has been under this form of treatment, which is now four months, the boy has remained at home and his behavior, according to his parents, has improved considerably. At present he smokes only six cigarettes in place of the thirty he used to use daily. He has stopped drinking, comes home before midnight, and has remained in one business position all the time.

Case II.—P. L., aged 15; father died two years ago of tuberculosis, mother and both sisters have endocarditis. No hereditary history of mental derangement. Physical examination, many stigmata of degeneration present—protruding ears, coarse hair, asymmetry of the face, high-arched palate, etc. —heart and lungs normal. Some time ago his mother brought him to the Children's Court as unmanageable. He would pick up rags in the street and sell them and with the money purchase cigarettes or beer. He would torment his sick mother and sisters, and to beat them was quite ordinary. He was very stubborn. The judge severely reprimanded him, made him promise to be good to his mother, stop playing truant, etc., and permitted him to go home on probation. After a few weeks of reform his mother was again compelled to take him before the judge with the same result. One day he was caught by a police officer stealing some pieces of lead pipe. He was arrested and brought before the same judge who sentenced him to thirty days in the Catholic Protectory. After his discharge he was placed under the care of a probation officer, to whom he reported frequently, and his conduct was closely watched. A few months ago this case was referred to me, after the mother again complained that the boy was hard to handle. I reasoned with the boy, tried to make a friend of him, gave him good thoughts, helped him with his school work. For eight days he was almost a model, and his mother thanked me for what I had done. As a reward, instead of asking the boy to call as before, daily, I told him to come every second day. Hardly had this scheme been inaugurated, when, during a visit to the mother, I heard he had entirely changed for the worse. In fact, he did not come to my office—I had to get him. After some more reasoning, I finally got him to take some medicine which would make him a good boy and keep him out of trouble.

This boy was exceptionally stupid, especially in mathematics and deductive reasoning. I tried to make him believe he would become brighter from the medicine. He received the same drugs as in the other case, viz., 1 grain of citric acid and 1 drop of nitric acid C. P. in a full tumbler of water three times a day. When I raised the dose to eight drops, he complained that it gave him vertigo, and I reduced it to five drops, which dose he is now taking. In addition, I arranged a working plan for every minute of the day. His arising and retiring as well as his play are apportioned definitely. In the beginning it was very difficult to have this program followed, but after various threats were resorted to I find it now works splendidly. His manners have entirely changed, but his dress is still very slovenly. He has become a much better student both in deportment and studies. I believe he is on the road to compare with other boys of his age.*

Among the other cases is one whose main fault was inability to articulate properly, associated with marked precocity. In this case there is some improvement also. In two cases of chronic hydrocephalus of two years' standing, following cerebrospinal meningitis, I have tried this remedy without result both by mouth and by injecting directly into the spinal space.

To conclude, out of thirty cases under my observation, in which I have thus far used this method of treatment, twelve are morally defective; eight are Children's Court cases from the Brooklyn Probation Association; eleven suffer various kinds of mental enfeeblement, four being very high-grade imbeciles. The other seven really are only backward or weak minded; two are choreic and three epileptic. So far eleven show decided improvement. In four there is some change for the better, while in six the children are decidedly worse. In the other cases I have not tried the treatment long enough to warrant any conclusion.

To be conservative, I only offer this method of treatment as a suggestion to the profession, and ask it be given a fair trial in conjunction with whatever schooling the children may require, after any removable physical defects have been properly treated. All of us know something must be done in this line by the doctor as a *physician*, not only by the teacher. If this paper does nothing more than stimulate therapeutists to work in a new direction, its object will be accomplished.

848 Greene Avenue.

PRIMARY MELANOSIS OF THE PALATE; NASOBUCCAL FISTULA OF RECENT SARCOMATOUS ORIGIN.†

By J. N. Roy, M.D.,
Montreal, Canada.
Physician to the Hotel-Dieu.

It is well known that there exist strange freaks of nature which till now the most profound observers fail to explain. In medicine, numerous examples could be cited; among others, primary melanosis of the palate is, I think, worthy of note. The histologist could easily tell us what melanosis consists of, but he would find it very difficult indeed to explain how and why that melanosis became primarily local-

*Since this paper was written I received a note from his school-teacher, saying she never had a boy in all her experience who tried so hard and made so much improvement as P. L.

†Paper read before the Canadian Medical Association, Montreal, September, 1907.

dh
epidemic, i
that even a i.

ized in the palate. Normally the mucous membrane of the human palate is of a pale rose color, and whenever pigment appears it is symptomatic of a pathological process.

A glance at comparative anatomy shows that, in general, the palate of animals is whitish in color, and the mucous membrane is undulated with numerous transverse furrows. However, the horse, the cow, the dog, the deer, and the fox may normally have a dark palate. The maki, on the other hand, has always a pigmented palate.

The caprices of nature must puzzle the biologist and make him wonder what could be the physiological explanation of how a white palate and a dark palate may exist in the same race of animals.

If the physiology of animals is so capricious, it is not at all the same thing with human physiology. With man melanosis of the palate has always a serious signification; either it is a precursory symptom of future disease, or it is a complication of an already existing tumor, or else it begins with the new growth.

Medical literature is very poor in references to this subject; I have been able to find only two other similar cases reported; therefore, I have thought it might be of interest to record the present case, and I would draw special attention to the beginning of this condition, which dates back twenty years, and to the nasobuccal fistula of recent sarcomatous origin.

In September, 1906, J. D., a blacksmith, 43 years of age, consulted me at the Hôtel-Dieu. He related that in 1886 he remarked on the median raphé of the vault of the palate a small round spot of a diameter of about three millimeters. This spot was not elevated and caused no trouble. A year before he had slightly injured his palate with the stem of a clay pipe. The hemorrhage was trifling and the wound healed quickly, apparently leaving no traces. During the following twelve years this spot increased in diameter to about six millimeters, without, however, becoming prominent. The only symptom he noticed was slight roughness to the tongue on pressure. He consulted a doctor, who prescribed gargles and applications of tincture of iodine. During the first twelve years, the melanosis was painless, but after the applications of iodine pain appeared. Pigmentation extended gradually to the surrounding parts, and the mucous membrane became granular and irregular. Hard, dark masses with a hemorrhagic tendency began to form. Four years later all the space between the dental arch of the superior maxilla was filled with melanotic granulations. The feeling of local irritation succeeded the pain caused by the applications of iodine, which were discontinued for that reason. The irritation disappeared temporarily when the patient rubbed the mass with his tongue. The last four years the lesion became deeper. Till then the whole palate was in a state of melanosis. Then slowly there came a depression more marked on the left side. We cannot trace at present any swelling antecedent to this depression. The palate then became rougher and furrows separated small masses, which apparently were increasing in size. Early in September last, the patient, while attempting to suck, perceived the existence of a nasobuccal fistula. Neither hemorrhage nor suppuration were noted.

On examination it was remarked that the melanosis invaded the whole hard palate. Granulations of a brown and black color and of various sizes were scattered around. They were hard and showed no tendency to hemorrhage. The left side was greatly depressed, and at the union of the anterior two-thirds with the posterior third the probe passed into the left nasal cavity. Pain was felt only if irritating food was taken, or if cold air passed quickly through the fistula. There was a slight discharge and slight necrotic odor. A mass of granulation tissue at the orifice of the fistula prevented liquids from entering the nasal cavity.

The voice was nasal. Taste was dulled; no dysphagia, but loss of pharyngeal reflexes. Gums and checks showed no melanosis.

The patient has always been a great smoker; he used to chew tobacco, and took no care of his teeth, which are quite discolored. The upper teeth are healthy, except the first left molar, which shows caries to the third degree. The third right molar has been extracted. The second left lower molar has also been extracted. The other teeth are quite healthy.

An anterior rhinoscopic examination shows a hypertrophic rhinitis on the left side. The septum is depressible and edematous, and a small cartilaginous spur prevents the perforation being seen. On the right side the septum is in the same condition, and there is hypertrophy of the inferior turbinals. There is no history of epistaxis or nasal discharge.

Posterior rhinoscopy shows hypertrophy of the posterior ends of the lower and middle turbinals. The posterior end of the septum is tripled in diameter. A whitish infiltration appears to come from the middle part of the septum, and gradually grows more marked as it extends backwards.

At this rhinological examination I found no melanosis. The pharynx is slightly congested, the larynx normal.

Diaphanoscopic examination shows the right antrum to be transparent and the pupil luminous. On the left side the cheek is darkened and the pupil obscured. By means of Mahu's method I examined the capacity of the left antrum, and found it held two cubic centimeters of water, which returns from the left nostril quite clear.

The cervical lymphatic glands on left side appear slightly hypertrophied. A close examination of the eyes shows they are normal. The iris is of a clear, gray color without any abnormal pigmentation.

Refraction is: Right eye, $90° + 0.25$ V = 1; left eye, $90° + 0.25$ V = 1.

The patient has always resided in the country and has enjoyed excellent health. The only sicknesses he has had were pneumonia in 1888 and mild cystitis in 1894. There is no history of tuberculosis or lues. He has made use of alcohol without abuse.

Married for eleven years, he is the father of seven children. The two eldest died of convulsions in infancy. The others are in good health. All his ancestors lived to a good old age. There is no cancerous history. His brothers and sisters are in excellent health.

On inspection of the skin there are no pigmented spots. The skin is normal, except for a slight subicteric shade. The examination of the different organs shows nothing abnormal. Urine analysis shows a density of 1,022. There is no sugar nor albumin, but a trace of urobilin.

Examination of the blood is of no special interest. There is nothing abnormal about its composition, and the number of red and white corpuscles varies but slightly from the normal. The presence of pigment in the blood was negative to a most minute examination.

Till now, the cause of this palatine perforation remained obscure.

Although it was impossible to trace lues in this patient, I prescribed large doses of mercury and

iodide of potassium, awaiting the microscopic report on a small granulation removed for examination. Menthol and boric acid salve, and a mouth-wash of chlorate of potassium, completed the medical treatment. Hygienic treatment consisted in forbidding all irritating food and ordering cleansing of the teeth.

In this case we did not think it necessary to search for the *Spirochæta pallida* of Schaudinn, as it is generally admitted that this microorganism is found only in primary and secondary lesions. As to the bacillus of rectilinear shape, its presence is questioned in tertiary lesions.

My friends, Dr. St. Jacques, professor at Laval University, and Dr. Hingston, F.R.C.S., Ed., returned the following report upon the small piece removed:

"On microscopic examination, the section appeared to measure about 5 millimeters in diameter. The epithelial layer still remains, though varying in thickness in some parts. The cells of the deeper layers are in general well divided from the underlying parts, but in some places they appear to merge into the submucous tissue.

"The submucous space is filled with cells of irregular shape, various size and appearance. In some places they are very close to each other; in others they are well separated. Some of the cells are round, others very irregular. Mitosis is not marked. The nuclei vary much in size and shape. The intercellular spaces are filled with granular substance, and here and there are seen, free blood corpuscles. In one place there are mucous glands altered in shape, but showing no signs of malignancy. Blood-vessels are scarce, but blood is seen in spaces without vessel-walls, as found in sarcoma. The cells of this mass are spread with no order whatever. Melanotic pigment is seen, and is both intra- and extracellular.

"Diagnosis: Melanotic sarcoma resembling melanotic endothelioma."

Seen again in November last, the patient said he was in the same state. The lesion appeared to have become deeper, especially anteriorly. The vault of the palate was becoming denuded, and in places small necrotic masses of bone were seen. There remained very little sensitiveness on the left side. He was very anxious to hear the result of the microscopic examination, and knowing that his condition was serious, he told me he would not consent to operative interference. He was given the necessary explanations, and the gravity of his state made clear. Operative measures were discussed, together with the necessary mutilation, possible complications, and probable recurrence. Having again refused the operation, he was given hygienic advice. A resorcin gargle and Fowler's solution were prescribed.

He returned to the country where he now lives, and came to see me in February and April. As yet there is no pain, but the lesion is rapidly increasing. The vault of the palate is becoming more denuded, and small sequestra become detached, thus increasing the size of the fistula. This atypical sarcoma, so long indolent, appears to be making up for lost time, and makes us foresee a fatal ending in the near future.

This case appears to be of interest from several points of view. First, should we put the beginning of this melanosis back twenty-one years, and look upon it as consecutive to injury received at that period? We know that all cutaneous regions strongly or chronically irritated can become pigmented, whether the irritation be physical, mechanical, or pathological. Could that law be applied to our case? It would be difficult to admit it, as the tissues of the human palate have not the property of producing melanotic pigment.

Should we call in a parasitic theory or attribute the cause of this melanosis to the melanin of the blood? Any hypothesis we could lay down would be most problematical, for, we must admit, our knowledge on the etiology of this condition is extremely vague.

This neoplasm surely did not begin with the melanosis, as it is generally admitted that melanotic sarcoma has a very rapid growth. By the clinical history we see that the pigmentation dates back twenty years, that the evolution was very slow, and that the symptoms were slight. Sixteen years after it had appeared the spot was only six millimeters in diameter, and was on a level with the mucous membrane of the palate. Perhaps the irritating action of the iodine caused the increase of the growth of the tumor in breadth and depth. Perhaps it was mere coincidence. The nasobuccal fistula appeared September last, and since then has rapidly progressed. From these facts I am inclined to think that this primary melanosis was benign in nature, and that in late years a neoplasm appeared in this location and became infiltrated with pigment, and gave to this lesion an invading, destructive, and openly malignant growth.

Dalbet affirms that all melanotic tumors arising elsewhere than in the eye and the skin are sarcomatous. The microscopic examination of tissue removed a year or two ago would have been of great interest. Perhaps at that moment we should have found an endothelial tumor. Pathologists do not agree on the histological transformation of endothelioma and sarcoma. Monod and Arthaud hold that sarcoma is an aggravated form of endothelioma. At present our tumor is certainly sarcomatous, although in places an arrangement of cells resembling endothelioma is found.

What is the prognosis? We know that of sarcoma the melanotic variety is one of the most serious. Moreover, when the growth invades the palatine vault and perforates it, the evolution is rapid, and invariably has a fatal termination.

If operative measures had been attempted recurrence probably would have taken place on account of the growth of the lesions towards the nose and left antrum. We should also have had the risk of post-operative complications and considerable disfiguration.

In conclusion, I should like to remark how unusual this case is, presenting a primary melanosis of the palate without coexisting lesions of the eye or skin, a slow evolution of twenty years, and a recent rapid sarcomatous growth.

STREPTOCOCCEMIA ACCOMPANYING APPENDICITIS.*

By DAVID SHEITLIS, M.D

NEW YORK.

ASSISTANT PATHOLOGIST, BETH ISRAEL HOSPITAL.

Septicemia as an accompaniment of appendicitis is not rare, and in the vast majority of cases occurs by the extension of the inflammation to the veins of the mesentery of the appendix and results in their thrombosis. These thrombi may either extend into the larger veins or may become infected and propagate emboli to liver or lungs and secondarily cause sepsis.

The case which I am reporting is exceptional, inasmuch as the septicemia did not occur through a

*Read before the Eastern Medical Society, March 8, 1907.

process of thrombosis but by a direct infection of the blood stream from a streptococcus appendicitis. In searching through the literature on the subject I was unable to find a similar case, while I met numerous cases of the former kind.

That the streptococcus is a habitant in healthy, as well as in diseased, appendices is well known. Hodenpyl, in reviewing thirty-five cases, eleven of which were his own, found the colon bacillus thirty-two times, the streptococcus with the colon once, the streptococcus alone once. Lantz, in a series of 138 cases, found the streptococcus in association with other bacteria forty-nine times. In twenty cases of appendicitis which I have examined bacteriologically, the streptococcus was encountered five times in association.

Just as in other situations, under favorable conditions, these organisms will increase in number and virulence. This is possible when the appendix itself is inflamed from whatever cause. A loss of continuity in its mucous membrane forms a channel of invasion of these bacteria into the lymphatics or blood-vessels directly, causing either a local or a general infection.

It is true that in most cases of infection of the portal system, the bacteria are arrested in the capillaries of the liver or even destroyed there, for the liver can well take care of bacteria and they seldom pass through it. According to Petrone and Pagona, the liver has a protective function against vegetable alkaloids, many mineral poisons, most bacteria and their toxins. This protective function is referred by some to the activity of the liver cells; by others to the endothelium of the capillaries and to the amount of glycogen stored in the liver.

In cases of virulent infection, I believe the protective action of the liver may not be sufficient to hinder the passing of microorganisms through it. Again, in those rare cases where an anastomosis exists between the portal and hepatic veins, this function of the liver would not come into play and the bacteria will pass into the systemic circulation directly.

Another explanation of a systemic infection in appendicitis is possible in those cases in which an anastomosis is present between the blood supply of the appendix and the iliolumbar, pelvic, or spermatic veins. Any of the above possibilities may have been present in the case which I am reporting, although it was impossible to determine the definite route.

H. S., a women, aged thirty-eight years, married, admitted to the Beth Israel Hospital, September 21, 1906, in the service of Dr. D. Robinsohn, to whom I am indebted for the clinical report of the case. The family history is negative. The patient is of good habits; hygienic surroundings poor. Menstruation always regular. No abortions; six children, youngest, two and a half years of age. Last menstruation two weeks ago. She had the usual diseases of childhood.

Six days ago, after a heavy meal, the patient began to feel indisposed. The following day she had a chill followed by fever, headache, intense thirst, nausea, some abdominal pain and prostration. There was no cough, dyspnea, or vomiting. The headache was frontal and persistent. The fever was continuous. Urination normal. Bowels constipated.

On admission the patient was fairly well nourished, skin moist, no eruption, slight dyspnea, flushed face, marked prostration. Ears and mastoids negative. Tongue moist and coated. Moderate congestion of throat. Inguinal glands enlarged.

Heart and lungs showed nothing abnormal. Liver dullness commenced at the fourth intercostal space, flatness at the sixth rib and reaching one inch below free border; the edge was indistinctly palpable and tender. Spleen was not palpable. The abdomen was uniformly rigid, tenderness in right hypochondriac and appendicular regions; slight tenderness in splenic region, tympanitic; no masses. The points of tenderness were not constant.

Vaginal examination showed the uterus normal in position and size. A globular tender mass was felt in the posterior fornix, somewhat more to the left. Rectal examination revealed the same mass (later proved to be a prolapsed ovary). The pulse on admission was 100; it varied during the first week between 100 and 120, increasing in rapidity during the second week to from 120 to 136. Respiration, 24 to 40. Temperature, remittent at first resembling a third week of typhoid, then irregularly intermittent. The urine was straw colored, and specific gravity 1012, no albumin or sugar; microscopically, no casts. Subsequent examination negative. Blood examination showed an initial leucocytosis of 7,400, increasing to 13,000 on the fourth day; last examination four days before death, 24,000, with a polynuclear of eighty-six per cent.

September 25. Four days after entrance the patient developed pain in the right shoulder and elbow joints with redness, swelling, and tenderness.

September 28. A blood culture was taken in glucose bouillon and the streptococcus together with the *Staphylococcus albus* found. The course of the disease now was marked by severe daily chills, vomiting, periods of apathy alternating with delirium. Over the right lower lobe slight dullness and numerous crepitant râles were heard.

October 3. Marked edema of left lower extremity, tenderness over tibia and along femoral vessels (thrombosis of femoral veins). Slight edema of right leg.

October 5. Another blood culture was taken in bouillon and in glucose-bouillon flasks, and on agar and two per cent. glucose-agar plates; all contained the streptococcus in pure culture, three or four colonies to one c.c. of blood on the solid media.

October 6. The patient was curetted because of suspicion of abortion; the débris examined showed normal endometrium, and was bacteriologically negative. Pus from a bulla on the forearm several days before death contained the streptococcus in pure culture.

The terminal course of the disease was that of increasing stupor, diarrhea, incontinence, with the thrombosis and arthritis becoming more marked.

The case was, therefore, one in which the constitutional manifestations were so prominent as to obscure the original seat of the disease. The diagnosis on admission was typhoid fever; the general appearance, the persistent headache, delirium, low leucocytosis, and absence of physical signs in chest were in favor of typhoid fever. The sudden onset with chill, absence of Gruber-Widal reaction were against it. In her subsequent course she presented a picture of sepsis. In the diagnosis of the case, portal thrombosis, subphrenic abscess, and appendicitis were considered; the objective signs, however, were neither definite nor constant. As above noted, sepsis of uterine origin was also suspected.

Autopsy performed by Dr. I. Strauss, pathologist. Rigor mortis, marked, no petechiæ, edema of both lower extremities but especially of the left.

Heart, size normal; muscle pale; one cusp of the tricuspid has a minute vegetation, another a slight erosion. Aortic flaps thickened. Pleuræ, normal. Lungs, edema, hypostatic congestion; a few areas of bronchopneumonia in right upper lobe.

Liver slightly enlarged, punctate hemorrhages on surface; on section showed slight parenchymatous degeneration. Pancreas negative. Suprarenals normal. Kidneys, surface smooth, showing numerous petechiae; capsule not adherent, on section cortex swollen, pale yellow in color, markings indistinct, minute hemorrhages. Stomach and intestines normal. Appendix, five inches in length, distal end distended, clubshaped, with recent adhesions at tip; on incising about a drachm of pus escaped. No thrombosis of the vessels of the mesentery or of the portal system could be found after careful search. Spleen enlarged, flabby and congested; surface and cut section presents numerous small hemorrhagic areas.

Uterus, normal in size; mucous membrane shows signs of recent curetting. Tubes normal; several veins of broad ligament thrombosed (recent). Ovaries, right enlarged, held dermoid cyst. Left also was cystic, containing hair and sebaceous matter, and was prolapsed.

Spreads made from the pus in the appendix showed streptococci and gram negative bacilli; from the spleen showed streptococci only.

Cultures from heart blood and spleen gave the streptococcus in pure culture.

Under the microscope the uterus showed marked congestion; the tubes were normal. The mucous membrane of the appendix was almost completely gone; submucosa infiltrated with mononuclear and polynuclear cells. Kidney, marked degeneration of convoluted tubules with hemorrhages in cortex.

The absence of thrombosis in the mesenteric or in the portal venous system; the absence of secondary foci in the liver, and the fact that no other focus was found that might be considered primary, justify the classification of this case as one of direct blood infection from the appendicitis.

The thrombosis of the veins in the broad ligament, like the femoral thrombosis, was probably secondary to the septic state.

Preservation of Leeches in Winter.—According to a reliable authority the following singular plan is adopted among the Siberian tribes of Russia for preserving leeches during the winter season. The mode appears, as far as practicable, to be worthy of imitation, as so much complaint is made of the difficulty it is intended to obviate. In October, a pit is dug, in marl or clay, in the open air, and the sides and bottom are made perfectly hard and smooth; it is then filled with fresh river water, the leeches are placed in it, and the whole mass of water is allowed to freeze to solidity. Whenever any of the leeches are required, a piece of ice containing them is chopped out of the pit, and is allowed to thaw gradually in a cool place. The leeches do not injure by this freezing, but will bite with greater readiness than those kept in a room during the winter.—*The Lancet.*

Treatment of Bone Cavities of Osteomyelitic Origin.—G. Rottenstein gives the origin of bone cavities as septic and aseptic, the former predominating. The aseptic arise from removal of tumors and gummata; the septic from tuberculosis and acute or chronic osteomyelitis. Duration may be very chronic. The bone is profoundly infected, and can with difficulty be disinfected, while the neighboring tissues are riddled with fistulous tracts and the skin is thinned and adherent to the bones. Sterilization is almost impossible. Various methods have been proposed to fill up the cavities: the autoplastic, the introduction of a foreign substance, as in dentistry, and substitution. The best method so far proposed is that of Mosetig-Moorhof, which the author has made use of in several cases. It depends on the substitution in the cavity of an absorbable, antiseptic material, which can be run in liquid without injury to the tissues and will then harden in the cavity. The material is composed of iodoform, sixty parts, oil of sesame, forty parts, and spermaceti, forty parts. The mixed materials are heated at 80° C. until perfectly homogeneous. They harden at 50° to 60°. The mixture is liquefied when used by heating a few minutes over a water-bath. This mixture is reabsorbable, easy to prepare and to sterilize, and easy to handle, while it liquefies at a low temperature, at which the iodoform is not decomposed. It fills all the interstices of the bone and makes the limb strong for use. The material is at first irregularly placed in the cavity, as may be seen by the *x*-ray; next it becomes regularized, and a clear zone of new bone appears around it. The evolution is extremely slow, but in the meantime the limb is useful. Finally it disappears entirely and the bone is entirely restored. The important points in preparation are sterilization of the skin by repeated washings and alcohol dressings; hemostasis by an Esmarch bandage; removal of all diseased skin; drying of the cavity by curettage, and a blast of warm air projected into the cavity. After operation the antiseptic dressings are renewed up to three to six weeks, and then the limb is used. Cases of five years' standing show a useful limb.—*Révue de Thérapeutique Médico-Chirurgicale.*

Annular Gastrectomy in the Mediogastric Region; Indications, Technique, Results.—René Leriche says that mediogastric annular gastrectomy is a rare operation whose indications are restricted. Yet for selected cases it is the best possible procedure, giving the maximum of facility and safety. The indications for its performance are to be found in ulcer, cancer, and hour-glass stomach. In ulcer, annular resection is rarely necessary, because mediogastric ulcerations that involve both walls of the stomach are rare. If the ulcer occupies part of both surfaces of the organ annular mediogastric resection is the best procedure. Gastroenterostomy is useless. Ulcerations are generally operated on in the healed stage when cicatricial pouching has taken place. Biloculation demands the removal of the central ring of the stomach. This operation is rarely of use in cancer. It is the operation of choice in tumors localized on the faces of the stomach, not simply stenosing. The technique consists of ligature of the coronary, pyloric, and the gastroepiploic arteries. Large clamps are then placed upon the ends of the stomach so as to close the two end sections into pouches. The portion to be removed is then cut with scissors between the clamps. The gastric continuity is reestablished by sutures. The results in ulcers are not yet determined on account of the small number of cases of operation by this method. Out of 25 cases operated on for cancer the mortality has been 18.5 per cent. The remote results are excellent.—*Archives Provençales de Chirurgie.*

Suppuration of Fibromata of the Uterus.—Jacques Delage and E. Gaujoux state that suppuration of the uterus when primary is so rare that it has been estimated as occurring once in one hundred cases. It is very difficult of diagnosis and has no tendency to spontaneous recovery. The fever connected with it is moderate and regular and only the loss of flesh and failure of the general health aid in the diagnosis. Secondarily, it may be the result of gangrene and sphacelus. The causes are those which affect the nutrition of the tumor, such as pressure on the pedicle, torsion, or adhesions. The immediate cause is always an infection coming by way of the vagina or from outside the uterus. Pregnancy is often the cause of this infection, it occurring at the time of labor. In one of the author's cases punctures for ascites were the source of the infection. It may come by way of the blood or lymphatic vessels. The suppuration begins from without, involving the fibromuscular tissues about the tumor. There is no hope of cure outside of operation except by rupture into the intestine or vagina. Operation should be done as soon as the diagnosis is made.—*Gazette des Hôpitaux.*

New York, November 2, 1907.

CONTRADICTORY ADVICE TO CONSUMPTIVES.

THE great antituberculosis crusade now in process of organization throughout the world has already produced a flood of literature for laymen, but there are so many contradictions in it that the work is bound to be seriously hampered unless physicians come to a more nearly unanimous opinion on disputed matters in prevention and cure. For instance, the layman who is told that improvement takes place mostly in the winter, and not in the summer, is naturally bewildered by the almost universal advice to go South in the autumn, so as to have perpetual summer. It is also well known that in the northern mountains, like the Adirondacks, where such excellent results are obtained, there is a maximum of cloudy days and but little sunshine at any time, particularly in winter. The patient must be astonished, then, to hear that nearly every American text-book asserts that unstinted sunshine is an absolute essential for cure. It has been asserted that there are a minimum of cases and a maximum of cures in very rainy climates, such as our northwest coast and the northwest corner of Europe, yet almost every authority states that the ideal climate should have no rainy days. The cures obtained at North Brother Island, in the city, even in quite advanced cases, are said to be obtained "in spite of unfavorable conditions," but the layman will naturally ask why it is "unfavorable" if it cures so remarkably.

Burton-Fanning, in his work on "The Open-Air Treatment of Tuberculosis," mentions the fact that even in England the glare of the sun is very powerful in producing headache, anorexia, prostration, and even fever, and that protection from the summer sun is essential. It is rather bewildering, then, to the patient to be told by the majority of physicians that he must live in the sunlight in summer. Dr. Jno. E. White of Colorado Springs also says (*Archives of Physiological Therapy*, October, 1906) that the coolest places must be selected in summer, avoiding direct sunlight, and that he has proved that the "sun-bath" almost invariably raises the temperature. Others have reported adverse results of the sun-bath, even hemorrhages, but there are many who advocate its use, even to the naked body, and one New York physician advises clothing which transmits the light, so as to have a perpetual sun-bath.

Every little while there are articles published by men whose opinions cannot be ignored, stating that a moderate amount of alcohol is beneficial in all cases and a necessity when there is fever. Perhaps most physicians prescribe it, yet the literature for laymen often states that total abstinence is essential in treatment. It is also generally taught that alcoholic indulgence is a predisposing causative factor, but the recent report of the Phipps Institute says "that alcohol neither prevents nor cures tuberculosis is evident from the number of alcoholics who have come for treatment, and that it does not strongly predispose to the disease seems to stand out prominently from the vast preponderance of nonalcoholics among applicants for treatment," and it also states that there is no evidence of greater susceptibility in the children of alcoholics. Laymen might twist that into a proof of the old idea that total abstinence was a predisposing cause, but the above report wisely says that all extreme views must be abandoned. Even in selecting his food the patient must choose between the extremists who insist upon a process of excessive feeding, and those who advise a low proteid diet, or follow those who advocate merely a generous amount of food. Should a patient seek another climate, he is again bewildered by the contradictory advice, for he finds that about every place is advertised as advantageous except his home, while there are many who advise him not to leave home at all.

Surely there is need of greater uniformity in advice, for the average layman is unable to sift it out and reject everything except the few essentials on which there are no differences of opinion. It is well to remember also that there is a growing number of observations which seem to prove that what is good for one type, either blond or brunette, is not necessarily good for the opposite, but we have not collected sufficient data for good, safe conclusions, except on general principles. There is then another ground for differences of opinion, for, while a few observers are reporting adverse results in certain types in certain places, the mass of the profession is of opinion that complexion has no influence on the result. It must be very disquieting to a very blond patient, after reading that he can go anywhere from Sweden to Egypt, or from New York to Southern California, to learn from someone else that to go to a hot, sunny place is suicide. Perhaps it would be better to omit all reference to disputed points in literature intended for laymen, unless the two sides can be reasonably set forth.

DUPLICATION OF HOSPITAL APPOINTMENTS.

IN the *Lancet* of October 12, attention is called to a dispute which has arisen in Bristol, with reference to holding duplicate hospital appointments. There appears to be no restriction there as to the number of appointments a man may hold in different hospitals, except that in some instances an appointee cannot connect himself with another institution without permission of the authorities of the hospital to which he is already attached. A new Memorial Hospital is about to be opened, and its directors have made certain appointments of men already connected with the Bristol Royal Infirmary. Thereupon the directors of the Infirmary passed the following rule: "No member of the honorary staff shall hold any union or club appointment. No

member of the full staff shall hold any other professional public appointment other than professorship or lectureship at any university, college, or school. No member of the assistant staff shall hold any other general hospital appointment, nor more than one special hospital appointment."

Some of the Bristol medical men take exception to this new rule. The *Lancet* notes that in London no such rule is enforced, and although it believes that no man should hold more than two principal appointments, it takes exception to the clause, "any other professional public appointment other than professorship or lectureship at any university, college, or school." This, it says, would exclude examinerships and would, in fact, be a direct embargo by a charity on the way in which its honorary officers should spend their time when not employed in the service of the charity in question. The new rule was forcibly advocated by the President of the Infirmary, Sir George White, but the *Lancet* has looked up his business record in "Who's Who" and finds that he is connected in a principal capacity with several large business enterprises, as well as various eleemosynary institutions. Why, it asks, make such a distinction between professional men and laymen? Presumably Sir George is efficient in all his several capacities, but may not a physician be equally efficient under similar circumstances? Certainly a conscientious medical man would not undertake more than he could perform, and would not be tolerated if, in his endeavor to hold appointments in several institutions, he failed in his duty in any particular instance.

Here in New York, this question has not, so far as we know, ever been under serious consideration by any hospital managers. The competition for appointments is so keen, and the supply of good men so ample, that no hospital has any difficulty in securing an attending staff which performs its duties with proper efficiency. The objection to the holding of several appointments in different hospitals by one man comes, not from the hospital authorities, but from the men who are unable to obtain one of the coveted positions. These men argue that no one in active private practice can spare the time for good work on the attending staff of more than one large hospital, and if he takes two or more such positions he must necessarily slur his work more or less, while at the same time he is keeping out one or more other men who would gladly devote the necessary time to the duties of such a position, thereby increasing their own experience and giving the hospital acceptable service.

THE ACTION OF CHRYSAROBIN ON THE KIDNEYS.

Since chrysarobin is used extensively in various skin diseases, especially psoriasis, the question as to whether it is absorbed, and, if so, whether it causes renal disturbances, is still undecided. In books on dermatology we find no, or only uncertain, information on the subject. Crocker, Jackson, Hyde, Montgomery, and Pusey, among others, make no mention of any effect on the kidney. Lesser and Neisser state that they have seen a nephritis distinctly due to chrysarobin. Thompson gave five grains [illegible] and caused gastrointestinal, but no renal disturbances. Kaposi and Von Düring each mention a case of nephritis which set in after the use of chrysarobin, but only after the latter had caused a severe dermatitis. The experiments of Lewin, Rosenthal, Müller, and Weyl on animals are probably responsible for the opinion that chrysarobin has a bad effect on the kidney, they having caused a parenchymatous nephritis by giving it internally.

Winkler (*Correspondenz-Blatt für Schweizer Aerzte,* September 15, 1907) has again taken up this subject. He gave rabbits from one to thirty grains internally for some time; it caused no nephritis, though chrysophanic acid was found in the urine; on applying a six-per-cent. ointment externally neither chrysophanic acid nor albumin was found in the urine; thus it was absorbed in the one case and not in the other, but caused no renal disturbances in either. He found that in man three-tenths of a grain internally would not cause any gastrointestinal symptoms, nor would chrysophanic acid or albumin appear in the urine; one grain caused gastrointestinal symptoms with no change in the urine; one and a half grains caused gastrointestinal symptoms and the appearance of chrysophanic acid, but no albumin or casts, in the urine. A ten per cent. ointment applied externally in man was not followed by either chrysophanic acid or albumin in the urine, so that chrysarobin is absorbed only when given internally, and even then does not cause nephritis. Winkler's observations in man confirm those recorded in the literature, while his observations in animals differ from those of Lewin and others. The kidneys are therefore apparently not in danger of being injured by chrysarobin, as it is used in psoriasis, but nevertheless Winkler recommends examining the urine before and after using it.

Angina Pectoris and Anginoid Conditions.

The overwhelming pain and the sense of impending death that are such prominent components of the clinical picture of angina pectoris have always been obstacles to the accurate analysis of the symptom complex as a whole. The physician is usually too busily occupied in bringing relief as rapidly as possible to take time to study critically the various phases exhibited by the manifestations of the disease. Schmoll (*Münchener medizinische Wochenschrift,* October 8, 1907) points out that numerous motor, sensory, and vasomotor symptoms occur in angina pectoris, and that these will be found to correspond to the peripheral zones, which themselves correspond, according to Head's researches, to definite spinal segments. To a slight degree these disturbances persist even during the intervals between the attacks, and in the author's opinion they are due to reflex stimulation of separate spinal segments through the filaments of the sympathetic nerves entering the cord at these levels. The sensations produced are accordingly projected to the periphery, and are experienced in the areas corresponding to the spinal segments. Anginoid symptoms must not, therefore, be regarded as definite evidence of coronary arteriosclerosis, for they indicate simply the response of the nervous system to disease of the left side of the heart. While the pathogenesis of angina due to coronary sclerosis is the same, clinically differences exist between the two types of cases. The anginoid symptoms are characterized by more or less periodicity in recurrence, the attacks

last hours or days, and are not so dependent on exertion and excitement as those of coronary sclerosis. They also develop more gradually, and the sense of impending death is absent or is less pronounced. Sometimes, of course, those criteria are unreliable, especially in aortic sclerosis and insufficiency, and then the differential diagnosis is dependent on the course of the disease.

The Period of Infection in Typhoid Fever.

At a time when less was known in regard to the behavior of the bacilli causing typhoid fever, it appeared that nothing could be simpler—theoretically at least—than practically to exterminate the disease. As long as it was supposed that, in order to avoid dissemination of the infection, it sufficed to sterilize the patient's excreta and the objects that might be contaminated with these, the problem of prophylaxis did not seem to present alarming proportions, but unfortunately the conditions are not so obligingly simple. The recognition of the facts that persons who have recovered from typhoid fever continue to excrete the specific organism in the urine and feces for indefinite periods, and that even persons who apparently have never had the disease, but have been in proximity to those who have, may carry about and excrete the bacilli, has very much complicated the question. A possibility, or rather probability, that still further increases the difficulties of combating the infection is involved in a recent communication by Conradi in the *Deutsche medizinische Wochenschrift*, October 10, 1907. As the result of the analysis of the conditions encountered in 600 cases coming under his observation in southwestern Germany during the past two and a half years, he has reached the conviction not only that infection is transmitted most often during the earliest days of the disease, before its true nature has been recognized, but also that it probably frequently takes place during the period of incubation, since the bacilli are already in the blood at this time, and are, or may be, excreted while the individual is still apparently in good health. Even if these views should find confirmation, however, they should not be regarded as reasons for discouragement, but rather as incentives to still greater thoroughness in the application of those prophylactic measures that are available.

Aseptic Operating.

An interesting comparison in regard to operative techniques is reported by Schenk and Scheib in the *Münchener medizinische Wochenschrift*, October 1, 1907. About six years ago Schenk and Lichtenstein made a series of bacteriological tests on laparotomy wounds, in order to determine how much bacterial contamination existed in apparently aseptic wounds. Portions of the skin near the incision, of the fat in the depths of the wound, and silk threads left in the wound and drawn out later, were examined, and it was found that the number of sterile wounds was really very small—for example, in forty-three cases the threads were sterile only eleven times. At that time the operative technique comprised only the ordinary measures, and recently another set of tests was made under conditions in which all the refinements of modern operating, including face masks and hoods, rubber gloves covered by cotton gloves that were frequently changed, and a complicated system of skin and hand disinfection, were used. The patient's skin was also covered with a rubber varnish. The results showed that, although the number of cases in which skin staphylococci occurred had been somewhat reduced, the proportion of sterile wounds was not very different from before, and the number of cases with nonfebrile postoperative course was also not markedly greater. It appears that wholly germ-free operating is not yet possible, even under the most rigid precautions, though it does not necessarily follow that it is therefore permissible to neglect any of these or to regard them as superfluous.

The Technique of Spinal Anesthesia.

In the production of spinal anesthesia two factors which are of great importance are the amount of cerebrospinal fluid removed and the solvent used for the anesthetic employed. Cases are on record in which too rapid an escape of the fluids caused severe headaches in adults and convulsions and shock in children, due probably to the sudden resulting hyperemia of the brain. Moreover, removal of too much fluid causes too rapid distribution of the anesthetic used and sudden action upon the medulla, instead of the gradual anesthetic effect which is more desirable. Writing in *Russkii Vratch*, B. H. Tomashevski says that of all solvents the best and most logical is the cerebrospinal fluid itself. He describes and pictures an apparatus by which the amount of the liquid withdrawn is measured directly. It consists of a graduated syringe attached perpendicularly to a modified spinal trocar of Bier. After the trocar is introduced, its stop-cock is closed and another one leading into the graduated syringe is opened. If the liquid withdrawn is to be used as a solvent for the anesthetic, the latter is introduced in the dry state into the syringe before the operation, having been sterilized by heating for one hour at 100° C. for two successive days.

News of the Week.

Dr. Bulkley's Annual Lectures on Diseases of the Skin.—The Governors of the New York Skin and Cancer Hospital, Second avenue and Tenth street, announce that Dr. L. Duncan Bulkley will give a ninth series of "Clinical Lectures on Diseases of the Skin," in the Out-Patient Hall of the hospital, on Wednesday afternoons from November 6 to December 18, 1907, at 4:15 o'clock. The course will be free to the medical profession.

Report of the Royal Commission on Tuberculosis.—In a second *ad interim* report, the Royal Commission on Tuberculosis suggests that there are two forms of the disease, one of which is rapidly fatal and the other tending to undergo spontaneous cure. The cable despatches state that the report contains an account of elaborate inoculation experiments carried out by Dr. Cobbett on a variety of animals with human tubercle bacilli. The results were remarkable and constant. One group of bacilli caused a rapidly fatal general tuberculosis. The other, when given in far larger doses, had only a slight local effect, tending toward spontaneous cure. The report does not assume that any new discovery has been made, but the results tabulated suggest that further experiments may establish that there are two types of the disease, having a different prognosis from the very beginning.

Cart-Tail Antituberculosis Addresses.—A novel means of displaying an itinerant tuberculosis exhibition has been organized under the auspices of the Kensington Tuberculosis Dispensary of Philadelphia and the Kensington branch of the

Y. M. C. A. During the noon hour a course of lectures will be delivered to the mill workers in the northeastern districts of Philadelphia from a wagon fitted with a suitable exhibit to illustrate the points made by the speakers.

Plague in San Francisco.—According to announcements made by the officials of the Marine Hospital Service, the plague situation in San Francisco shows little change. The efforts at rat extermination by means of phosphorus paste and a mixture of equal parts of plaster-of-Paris and flour, are beginning to show good results. The authorities in Oakland, Alameda, and Berkeley are taking measures to prevent the spread of the plague on their side of the bay. The sum of $10,000 has been promised by the City Council of Oakland as a monthly expenditure to prevent the spread of the disease. The campaign will consist of a sanitary survey, an inspection of the dead, necropsies of all bodies which are considered suspicious of plague, and general measures for the destruction of the rat and its parasites.

Prevalence of Diphtheria in Chicago.—According to the weekly bulletin of the Health Department, diphtheria is spreading in this city. Reports of 127 cases were received last week, against 96 for the preceding week. To check the disease the City Health Department announces that it will prosecute persons who do not obey quarantine regulations. In explanation of the spread of the disease, the bulletin says: "Patients recently recovered from the disease, and with diphtheria bacilli still in the throat, are being allowed to associate with well children. Virulent bacteria not infrequently remain in the throat for days after the membrane has disappeared and the child feels well. During these days the child is just as dangerous to other children as at any time of its illness."

Free Antitoxin in Illinois.—There have been 105 stations in 102 counties of the State established for the free distribution of antitoxin by the State Board of Health. It is said that 100 more are to be established at an early date out of the $15,000 annual appropriation.

Smallpox and Yellow Fever.—From June 28 to October 25 there were 5,039 cases of smallpox in the country. Of this number only sixteen were fatal. Between September 1 and October 25 two cases of yellow fever were reported, one at Baltimore and one at Fernandina, Fla. Death resulted in one of these cases. Both patients were aliens, arriving on steamships from Cuba.

Scarlet Fever in a Pennsylvania Town.—An epidemic of this disease is causing alarm in Glen Lyon, a mining town about ten miles from Wilkesbarre. Seventy-five cases and twenty-eight deaths have already been reported.

The Russian Cholera Outbreak is reported as especially severe at Kieff, where it is causing hundreds of deaths daily.

An Antivivisection Play.—In one of the Berlin theaters a play was produced last week with the title "For the Sake of Humanity," and intended to excite interest in the antivivisection propaganda. One of the two authors is a Berlin physician. The play has as its leading character a worker in experimental medicine, who, in one episode said to be reminiscent of Irving's nightmare scene in "The Bells," is haunted by a dream in which he sees the specters of his experimental subjects.

A Hazardous Experiment.—The newspapers announce that one of the London slot machine companies is preparing to install in public places apparatus designed to furnish small quantities of milk on the deposit of a coin. It is stated that the apparatus is so constructed as to render it easily kept clean, but the possibility of conducting such an enterprise without its becoming a danger to public health seems very remote.

Award of Damages for Alleged Unjust Commitment.—In the suit of a woman residing in New City, N. Y., against two physicians, for $50,000, on the ground that they unjustly pronounced her insane, and were instrumental in causing her commitment to the Middletown Insane Asylum, the jury, after deliberating twelve hours, made an award of $25,000. This was in spite of the testimony of several experts declaring that the plaintiff was insane.

Organization to Increase Medical Fees Not Illegal.—The presiding judge has acquitted the Bower County, Iowa, physicians who were indicted for uniting in order to raise the scale of fees.

Michael Reese Hospital of Chicago.—The management of this hospital recently announced the adoption of the "open-door" method, so that now any physician or surgeon can take a patient to that institution for treatment, irrespective of whether the physician is on the staff of the hospital or not.

Bequests to Philadelphia Hospitals.—By the will of the late Isaac Saller of Philadelphia the sum of $1,000 is bequeathed to the Jewish Hospital Association and $500 to the Jewish Maternity Hospital.

New Hospital for Chicago.—A hospital accommodating 300 patients, and combining the best in modern hospital buildings and arrangement, has been planned by the Lithuanian-Americans in Chicago. While it will be built by the Lithuanians, no line of nationality, color, or creed will be drawn. Six acres at Forty-sixth and Western avenues have been purchased for the site and an option is held on six acres adjoining. Inmates suffering with tuberculosis and other contagious diseases will be isolated. There will be one quadrangle for children, another for men, another for women, and special attention will be paid to the treatment of nervous diseases.

Christian Scientists Fined.—An adherent of the Christian Science cult and his wife in Mt. Holly, N. J., who were convicted recently of manslaughter on the charge of not providing proper medical attendance for their child, who died as a result of their neglect, have been sentenced to pay a fine of $100 each.

For a New Optometry Bill.—Representatives of the New York State Optical Society and of the Optometrical Society of this city have announced their intention of preparing a new optometry bill to be presented at the coming session of the Legislature. One of the objections to last year's bill which caused Governor Hughes to veto the measure was that it did not place the examinations provided for under the control of the State Board of Regents, and it is stated that the framers of the new bill intend to remedy this defect.

Rockefeller Institute.—The following appointments have been made to the staff of the Rockefeller Institute for Medical Research: Dr. Hideyo Noguchi promoted to Associate in Pathology; Dr. G. W. Heimrod, Assistant in Biological Chemistry; Dr. W. A. Jacobs, Fellow in Biological Chemistry; Mr. P. A. Kober, Scholar in Biological Chemistry; Dr. R. V. Lamar, Scholar in Pathology.

American Physiotherapeutic Association.—The first annual meeting of this organization will be held at French Lick Springs, Indiana, December 5, 6,

and 7, 1907. The secretary is Dr. Otto Juettner of Cincinnati, Ohio.

Sixth District Medical Association of Georgia.—The next convention of this organization will be held at Macon on November 13, 1907, under the presidency of Dr. John R. Shannon of Forsyth. The secretary is Dr. Eugene B. Elder of Macon.

Medical Association of the Southwest.—At its meeting held in Hot Springs, Ark., on October 12, this organization elected the following officers: *President,* Dr. Thomas E. Holland of Hot Springs; *Vice-Presidents,* Drs. S. S. Glasscock of Kansas City, Kan., B. J. Vance of Chicolah, Okla., S. C. James of Kansas City, Mo., and J. E. Gilchrist of Gainesville, Tex.; *Secretary-Treasurer,* Dr. F. H. Clark of El Reno, Okla.

Thurber (Mass.) Medical Association.—The following officers were elected at the fifty-fourth annual meeting of this society held in Milford on October 17: *President,* Dr. Charles H. Randall of Franklin; *Vice-President,* Dr. Halbert L. Keith of Milford; *Secretary,* Dr. A. J. Gallison of Franklin; *Treasurer,* Dr. C. B. Hussey of Franklin.

Restriction of the Sale of Cocaine in Illinois.—A new cocaine law has been drawn and sent to the Illinois Legislature. A bill prepared by C. H. Avery of the State Board of Pharmacy is designed to put the drug out of the reach of all but physicians. It differs from the present law in that it not only more accurately describes what is meant by cocaine, but imposes a heavy penalty for the illegal selling of it. It goes so far as to forbid physicians from prescribing the drug to persons known to be addicted to its use. The only legal sale to be allowed is on the prescription of a registered physician, which must give the name and address of the person prescribed for, the date it was filled, and be kept permanently on file by the druggist. It must be filled but once, and no copy of it made. The penalty for violations is a fine of not more than one thousand dollars or imprisonment in jail for a year, or both.

Civil Service Examinations.—The State Civil Service Commission will hold examinations November 16, 1907, for the following positions: Dentist, State Institutions; health officer, Village of Port Chester, $600; physician, State Hospitals, $900 and maintenance; trained nurse, State Institutions, $420 to $600 and maintenance. The last day for filing applications for these positions is November 9. Full information with application forms for any of these examinations may be obtained upon postal card request from the Chief Examiner of the Commission, Mr. Charles S. Fowler, at Albany.

Association of Erie Railway Surgeons.—At the recent annual meeting of this Association the following officers were elected: *President,* Dr. F. D. Bain of Kenton, Ohio; *Vice-President,* Dr. G. H. Witter of Wellsville, N. Y.; *Secretary and Treasurer,* Dr. B. F. Wakeman of Hornell, N. Y.; *Executive Committee,* Drs. S. Heilman of Sharon, Pa., C. E. Sawyer of Marion, Ohio, and H. F. Gillette of Cuba, N. Y. The next meeting will be held in Buffalo during October, 1908.

Obituary Notes.—Dr. Julian La Pierre of Norwich, Conn., died on October 21 of cardiac disease, at the age of sixty-three years. He was a native of Norwich and was educated at Bowdoin College. He was graduated from the Bellevue Hospital Medical School in 1871, and had practised in Norwich and vicinity ever since. He was a member of the Norwich Medical Association, New London County Medical Association, of both of which he had been president, and of the Connecticut Medical Society. During the Spanish war he was surgeon of the Third Regiment, Connecticut Volunteers. Since 1893 he had been visiting physician to the Backus Hospital. Dr. La Pierre took an active interest in educational and municipal affairs, and had served in several public offices.

Dr. Hosea J. Babbin, Medical Director, U. S. N., retired, died on October 25 at his home in Brooklyn. During the Spanish-American war he was president of the examining board at the New York Navy Yard. Later he was in charge of the Naval Hospital, New York, and was transferred to the retired list as a Medical Director with the rank of Rear Admiral. He was born in Canada and was a graduate of McGill and Harvard Universities.

Dr. Jeannette Reid Durkee died on October 27 at her residence in Brooklyn. Dr. Durkee was born in Binghamton, N. Y., but for the last fourteen years had lived and practised in this city.

Dr. Cushman Day of Brooklyn died suddenly on October 26 in Boston, at the age of thirty years. He was a graduate of Tufts Medical School, and for the past two years had been an interne in the Boston City Hospital.

Dr. Jas. F. Rhinehart of Oakland, Cal., died on October 14 after an operation for appendicitis. Dr. Rhinehart was a native of Springfield, Ky., and was born forty years ago.

Dr. Samuel D. Mercer of Omaha died on October 10, at the age of sixty-five years. He was born in Marion County, Illinois, and received his medical education at the University of Michigan and the Berkshire Medical College. He served in the Civil War as assistant surgeon, and in 1866 began practice in Omaha. He became chief surgeon of the Union Pacific Railway, was president of the Board of United States Pension Examiners, was secretary of the Nebraska Medical Association, vice-president of the American Medical Association in 1885-6, and was one of the founders of the Omaha Medical College. About a year ago ill health compelled him to give up active work.

Dr. Valentine Manahan of Enfield, N. H., died on October 15, at the age of eighty-two years. He received his medical degree from the Jefferson Medical College of Philadelphia and practised in Manchester, Antrim, and Springfield, remaining in the latter place fifteen years, until he came to Enfield in 1866.

Dr. R. O. Y. Warren of Butte, Mont., died on October 19, at the age of forty-seven years. He was a native of West Virginia, and was graduated from the Baltimore College of Physicians and Surgeons in 1885. He practised for a time in Missouri and then removed to Montana sixteen years ago. For ten years he was resident physician and superintendent of the State Asylum for the Insane at Warm Springs.

Dr. Dale Lucas of Kansas City, Mo., died on October 14 after a brief illness, at the age of thirty-two years. He was born in Hillsdale, Kan., and was graduated from the medical school of the University of Kansas in 1906.

The First Harvey Society Lecture.

The first of the third series of lectures of the Harvey Society was delivered on Saturday evening, October 26, in the large hall of the Academy of Medicine. The speaker, Professor E. O. Jordan of the University of Chicago, took for his subject "Problems of Sanitation." He began by reading a description of London twenty-five years ago. In this the dirty, crowded, ill-smelling streets, the dilapidated,

filthy houses, the dark and foul river which really was a monster sewer, dominated the picture. And yet London at this time was not the worst of the large cities. It was noteworthy that the severest criticisms made of the civilization of the nineteenth century related to questions of sanitation, of public hygiene. Even at that time, however, there was a marked improvement over conditions in the middle ages. The conditions then were almost incredible. Filth was everywhere, and was not even remarked. The personal habits of the people were filthy in the extreme. The streets were littered with rubbish of all kinds, with dead animals, garbage, and human excrement. And the death rates corresponded to these conditions. But as death and disease were regarded as the consequence of sin they were not thought capable of being diminished. Not until a scientific basis for the origin of infectious diseases was given by the germ theory did the views concerning disease and death change.

The campaign against disease could be carried on in various ways. Thus a great deal could no doubt be accomplished by individual nursing, by proper medical attendance, good food, etc. This had done in the past and would do in the future. As a mass method, however, it was not to be compared with the measures which we know under the head of preventive medicine. There were two classes of measures in the prevention of disease: (1) those dealing with the well-being of the individual and (2) those dealing with environmental conditions. *Personal* hygiene had necessarily to be largely a matter of education. It was therefore always a slow process. In connection with *public* hygiene it was well to remember that a stream could not rise higher than its source and that the demands should not be too great. Public hygiene should seek to provide for a group of individuals those conditions which the most intelligent of the group would himself choose.

It was instructive to note the relative frequency of certain causes of death, to get an idea as to what had been accomplished. The speaker then exhibited a table showing the order of the causes of death in Massachusetts in 1856 and 1904. In the former period consumption was first, scarlet fever next, typhoid fever came sixth, and dysentery seventh. In 1904 consumption had moved to second place, scarlet fever to twenty-first, typhoid fever to thirteenth, and dysentery to seventeenth. It was notable that the infectious diseases had so well receded. This was undoubtedly due largely to progress in public hygiene. This point was particularly well shown by the statistics of typhoid fever in Lawrence and in Albany. In both these towns there had been a marked decrease in the typhoid mortality since the installation of filters for the public water supply.

But we should not look to the achievements of the past; our concern was what to do for the future. In many instances there was still need for more thorough information. Thus in the case of typhoid it was seen that the mortalities from this disease were still much higher in this country than in Europe. This could be seen from the table. This showed the death rate from typhoid fever in certain cities:

New York	1.44		
Chicago	2.47	Hamburg	0.56
Boston	2.78	Berlin	0.43
Cincinnati	2.68	London	1.23
Lawrence	3.00		

The mortalities might therefore be called the "residual typhoid" mortalities. This residual typhoid was due to milk, flies, oysters, shallow wells, direct contact, and to bacilli carriers. An instance of this kind of infection was furnished by the experience of the city of Washington. Here an elaborate filter was installed in the water system in November, 1905. This was followed in 1906 by a higher typhoid death rate than in either of the preceding three years. So there was still considerable to learn in this disease.

In the summer diarrheas of infancy we had no doubt accomplished something by urging the advantages of pure milk and fresh air. But we did not know to what extent domestic infection was a factor. And what was the next step to be? Were we to work for certified milk conditions, or were we to pasteurize? In this connection the speaker called attention to the unreliability of many statistics on infant mortality. These were not accurate unless the birth rates were accurately known. It was notorious that in this country birth statistics were extremely unreliable. Two towns in Europe were compared. In these the infant mortalities calculated on the total population or on the total death rate gave figures that exactly reversed the conditions actually existing in the towns as shown by the calculations based on the birth rate. According to Newman, the infant mortality in England and Wales had not appreciably decreased in the past two decades. In this country both Boston and New York showed marked declines in deaths in infancy.

However, it was gratifying to know that the campaign of education was well under way. And in the gradual suppression of tuberculosis it had already achieved a great measure of success. The field of public hygiene was also becoming broader. At the present time we were still handling certain problems in too amateurish a way. Thus we should take more cognizance of dust and smoke in cities as they affect the respiratory organs, of noises and their effect on the nervous system; and violence still claimed far too many victims. The time was ripe also for dealing with dangerous trades, and with the dangers in shops from machinery generally. The employers should be made to realize that such action was not only more humane, but was far less expensive than the present system. In factories the cost of the slight modifications of the machinery to make them far more safe to handle was really trifling. In England twenty-four industries were recognized by law as being dangerous trades; in Germany their number was fifteen.

The public was gradually awaking to a realization of the fact that the public health is a matter of paramount importance. Unfortunately, it was still unable to appreciate that the service should be far better recompensed than it now is. Public health service should be made a distinct career, and should be made attractive to the right sort of men. The medical schools at the present time made too little provision for this branch of medicine, and yet it was fully as important as curative medicine, if not more so. It was to the everlasting credit of the medical profession that it did not falter when it came to the eradication of diseases, even though this meant fewer patients for the practitioner. The speaker said that the medical schools in connection with our large universities should combine courses in the medical school with courses in the engineering school, and so thoroughly equip men for a career in public health work.

At the conclusion of the address a vote of thanks to the speaker was moved by Dr. W. H. Park, after which the chairman announced the next lecture in the course, "The Etiology of Tumors," to be delivered by Prof. James Ewing of Cornell Medical School, November 16.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SIR SAMUEL WILKS AT GUY'S—THE KING'S SANATORIUM—THE NORMAN KERR MEMORIAL LECTURE—VIVISECTION REPORT, MR. COLERIDGE'S TRUTH—MEDICAL EXHIBITION—OBITUARY.

LONDON, October 11, 1907.

SIR SAMUEL WILKS, to the great delight of Guy's men, presided last Friday at the annual meeting of the Guy's Student's Physical Society. An address was delivered by Dr. G. A. Gibson of Edinburgh, in which he discussed the theories of Addison's disease. The facts, he said, showed a certain variability of clinical phenomena, and it seemed probable that a classification of the types might shortly be established. Recent investigations rendered it almost certain that the disease was due to a lack of internal secretion. The conception of the disease by the great man whose name had been fixed upon it was, from a clinical standpoint, almost complete. But the pathological explanation, which was long thought final, had been modified by changing currents of thought.

Sir Samuel Wilks proposed a vote of thanks and commented with his usual perspicacity on some of the points in the lecture, mentioning that it was Trousseau who proposed the name of "Addison's disease," and relating how Addison was able to refute the early objection of only "coincidence." Referring to blood pressure, he remarked that those who devoted attention to it should not forget the factor of the rapidity of the blood stream, for the pressure was really greater when the stream was slow. He thought there were more deaths from hemoptysis and cardiac disease at night, when the patients were lying down, than in the day, when they were erect and going about. The vote was carried by acclamation and in acknowledging it Dr. Gibson remarked that in examination of football players before and after playing the blood pressure had always been found to have fallen after the game. Speaking afterwards to a vote of thanks to Sir S. Wilks for presiding, Dr. Gibson applied to him the lines of Oliver Wendell Holmes:

> "For him in vain the envious seasons roll
> Who holds eternal summer in his soul."

The King's Sanatorium has now been open for more than a year and some details of the working have been made public. You will remember that it is due to the munificence of Sir E. Cassel, who presented the King with £200,000 to devote to such objects of philanthropy as His Majesty pleased. The King determined on a sanatorium for the accommodation of persons of slender means, in professional or other employments for which no provision existed. The purpose has been accomplished and persons of these classes attacked by phthisis have been treated with such success that they have returned to their ordinary avocations greatly benefited

The situation of the sanatorium is an ideal one and the building and its equipment are in accordance with the latest views on tuberculosis. Every person employed is periodically examined and the weight and state of health recorded. Patients are called at 7:30 A.M. and are on their balconies by 9:30 to see the medical officer and take his instructions as to their day's exercises. From 12 to 1 rest is compulsory. Luncheon follows and two hours' exercise after it—generally walking. Tea at 4 to those who like it. Then recreation with rest from 6 to 7 o'clock, followed by dinner at a quarter past, and bed at 9:30. As a rule, the patients eat as appetite may tempt them—no overfeeding being in favor—and indigestion does not seem so troublesome as in the other plan, so much favored in Germany. The patients usually have a better appetite after a week or two's sojourn and begin to put on weight—in some cases quite rapidly. Out of 206 patients discharged up to last month, 120 had returned to work and 16 died, while 59 reported that they were continuing the treatment. There is a research laboratory attached to the sanatorium, to which one may look for valuable investigations and records.

The Norman Kerr memorial lecture was delivered on Tuesday evening by Dr. R. W. Branthwaite, Inspector under the Inebriates Act. He stated that after 25 years' study of the subject he had come to the conclusion that inebriety is due to some inherent defect in the mental mechanism, mostly congenital but sometimes more or less acquired. This defect is brought into prominence by alcohol, apart from which it might remain hidden. He regarded it as doubtful whether habitual inebriety is ever really acquired in the absence of any pre-existing defect. "I am very skeptical indeed," he said, " as to the probability of any normally constituted individual becoming a habitual drunkard, even if he permits himself to indulge occasionally in a fair measure of careless drinking, without the intervention of nerve shock or other influence sufficiently potent to disturb the equilibrium of nervous and mental mechanism." The lecturer proceeded to state that out of 2,277 admissions to State and certified inebriate reformatories 62 per cent. were proved to be either insane or defective in varying degree and only a little over 37 per cent. could be described as of average mental capacity. As to the insane, he was satisfied that the majority had become alcoholics because of their tendency to insanity, not as a result of alcoholism, the preceding drunkenness being premonitory of the coming mental disorder. In the other class, the mentally defective, physical signs of arrested or distorted development were present and such cases always gave evidence of imperfectly developed moral sense and control over impulse, as well as defective judgment. Even those inmates classified as "of average mental capacity" could not be considered as entirely reformable; everything depended on the degree of defect. As to treatment, Dr. Branthwaite said influences on the moral resolution are useless unless the mental condition approaches the normal. Drugs are of extreme value to relieve symptoms during the transition from long-continued drunkenness to enforced sobriety. As to control, it was too often delayed too long; it should be resorted to before the defect is increased by degeneracy. Legislation, the lecturer said, had only partly achieved its purpose of substituting reformatory for prison treatment. Until this is further accomplished the Act will not be obtained. Earlier control is wanted without regard to the patient's opinion. The principle of guardianship, adopted in some countries, might be tried in England, and if that failed there should be power for compulsory committal to reformatories on certificate and evidence.

A third volume of minutes of evidence has been issued by the Royal Commission on Vivisection. This includes 12 days' sittings, and various witnesses were examined. Much of it is rather dull, but the sensational papers attach importance to the statements of Mr. Stephen Coleridge, who was under examination for three days and formulated twelve charges against the Home Office as to its administration of the Act. Now Mr. Coleridge has prated so much of the ethical and moral view that you might suppose him to be a person with a very sensitive conscience. Asked if he would accept inspection by a person of character, he said: "Certainly not; all these experimenters have the greatest contempt for the Act of Parliament. They deny a breach of the Act just as I do of the Motor Car Act. I drive a car, and when I go beyond the speed limit and a policeman asks me, I say no, I am not. Nothing will keep me from going beyond the limit except a policeman in the car and nothing will keep an experimenter within the Act except the inspector in his laboratory." Surely, said the questioner, if you gave your word you would not expect to be disbelieved? "I do not say so," he said. Lord Lelby observed, "You are not very ethical about motor cars," to which he retorted, "Vivisectors regard the Act in the same way." No doubt they will feel obliged to him for the comparison. But he has now revealed what credit is to be attached to his word when he describes the horrors he is paid to circulate by weaker people with more regard for truth.

The third Medical Exhibition organized by the *British and Colonial Druggist* was opened on Monday and closes this evening. Its success seems to have exceeded that of last year, when nearly 5,000 medical men visited the display. A commendable point in the administration is that it is only for medical men, and in order to keep it so those who receive invitations and are unable to attend are asked to destroy their ticket. Drugs, medical, and surgical appliances, and whatever is designed to add to the comfort of invalids, are found in the exhibition. Beds, chairs, couches, and other furniture of the latest designs are well worth inspection. The proprietors of the *Druggist* do the thing uncommonly well, even to providing a band and refreshments.

A committee of inquiry into the management of the Donegal asylum reports that an inmate confined there had been dealing in sheep, had hired land for grazing them, and is now the owner of a number of sheep kept on the said land. The report adds that the asylum attendants had hired land from this inmate for grazing their own sheep and that at frequent intervals the inmate had been allowed to go out to transact business at fairs in charge of attendants who were interested with him in sheep dealing. He had received a telegram of a sale in the asylum and been paid in the grounds by a purchaser. The committee recommended that his profits should be applied to the cost of his maintenance and a special meeting is to be called to consider the report.

Dr. George F. Elliott died on Sunday, aged 73. He was Consulting Physician to the Hull Royal Infirmary, in connection with which he worked for some 35 years, lecturing

also in the School on Practice of Medicine. He qualified in 1855, B.A. and M.B., Dublin, proceeded to the M.D. in 1866, and the next year obtained the M.D., Oxford. In 1875 he joined the London College of Physicians as a member and was elected to the Fellowship in 1883. In early life he served in the navy and was present during the blockade of the Baltic in the Russian war and also at the taking of the Taker forts.

Dr. John S. Nairne, F.R.C.S. and Consulting Surgeon to the Glasgow Women's Hospital, died on the 8th of September, aged 61. He was the father of the Glasgow Obstetrical Society, a far-seeing clinical observer, and skillful surgeon. He was, too, a scholar of great attainments. On retiring from active work a year ago he received a handsome testimonial from the community he had served through his life.

THE WINDOW TENT.

To the Editor of the Medical Record:

Sir:—The writer invented the window tent, but never used his name with it in print, and took out no patents on it. The name was suggested by some enthusiastic open-air advocates of Boston, who, with the writer's consent, used the affair in incurable consumption. They gave the writer a statement crediting him with the invention, and recently turned over to him complete records of thirty cases of confirmed phthisis, who, in the summer of 1901, were instructed in the use of the window tent. The window tent and its use were for the first time described in print in the Boston *Journal* and in the New York *World*, October 20, 1901, when the previous summer's use of the window tent was illustrated and described at length and in detail, without using anybody's name. While there is difference between inventing and creating, on the one hand, and copying and improving, on the other, the additions and improvements to the window tent, made in New England, the West, and New York, where invention is seemingly claimed, are both ingenious and philanthropic, and deserve universal vogue and commendation. This work has been done far better, I believe, than I ever could have hoped to accomplish it. Norburne B. Jenkins, M.D.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 17, 1907.

Treatment of Simple Infections of the Staphylococcus with the "Vaccines of Wright."—This paper, by H. F. Hartwell and R. I. Lee, presents the results of work done in the Pathological Laboratory of the Massachusetts General Hospital. The authors find that while in general the vaccine treatment is a very complicated process, it can be utilized in a simple manner in localized surface infections such as boils, carbuncles, and septic wounds. In practically all such cases it is fair to assume, say the authors, that the inoculating organism is the *Staphylococcus aureus*. It is not necessary to prepare the vaccine from the identical organism of the given case, but equally good results follow its preparation from a vaccine of the *S. aureus* from any source, practically a stock vaccine. Acting on this principle and basing their views on the results obtained in about 100 cases, they offer the following conclusions: (1) Treatment with vaccines is the most effectual treatment for boils and carbuncles. (2) Although the vaccine treatment does not prevent recurrence, cases of chronic furunculosis can be absolutely controlled by occasional inoculations. (3) Vaccine treatment is a valuable surgical adjunct in appropriate cases. (4) The treatment of this class of cases can be successfully carried out without the estimation of the opsonic index and without any special technical training.

New York Medical Journal, October 19, 1907.

A Contribution to Heredosyphilology.—R. W. Taylor contributes the history for a series of cases occurring in the same family, involving twelve individuals and extending over a period of 37 years. The salient points in the cases are the following: (1) The seeming benignancy of syphilis in the father and its malignancy and inveteracy in the mother. (2) The synchronous development of similar specific osseous lesions in two sisters, one a heredosyphilitic, the other a hitherto healthy child. (3) The evident effect of treatment of the mother upon gestation; death ensuing in two children when it was neglected, and seeming immunity being conferred when it was persisted in. (4) The development at the age of thirty of classical hereditary lesions, without antecedent manifestations on the subject, in whom there was no infection by the acquired disease. (5) The apparent escape of four successive children while the mother presented mild, sparse gummatous lesions which were moderately well treated. (6) The evolution of specific manifestations at the eighth and the sixteenth year in the last and tenth child, *K.*, who otherwise had been without a blemish during life, and had never had the acquired disease. The author says that these cases suggest the serious inquiry as to the ultimate fate of the survivors who seem to be in robust health and have never shown a blemish and to the ultimate condition of their progeny and adds that the facts he has narrated with reference to this particular family circle impressively emphasize the urgent need for active, prolonged medication of the syphilitic mother and father. These sources of disease and race deterioration should be more generally and thoroughly investigated and treated, he says, than they have been in the past.

Prophylaxis of Tropical Disease.—J. H. White of the Marine Hospital Service discusses this question with reference to leprosy, plague, and yellow fever, detailing under each heading what have been found to be the most practical and efficient means of checking epidemics. Concerning yellow fever he says that we now know positively the following facts about the stegomyia mosquito: (1) It generally breeds in artificial containers. (2) It prefers clean water, although under compulsion, that is to say, in the absence of clean water, it may even utilize a cesspool. (3) It has been classed as a really domesticated animal, and is distinctly a house mosquito that cannot stand the glare of the sun. (4) It thrives best in a humid climate. (5) It has no inclination to travel, and, while undeniably doing so, it is always as a matter of accident, its migrations, as a rule, being limited to feet rather than to miles. (6) It is almost certainly an exotic, and ought to be with absolute certainty, an exile. But in spite of all our knowledge and the various prophylactic measures thereby suggested, outbreaks of the disease will occur and the origin of many cases is obscured. Then we must have a thorough organization from sanitary forces, etc., essential features of which are (1) A central office in touch with all parts and provided with a perfect record system so that every detail may be referred to at a moment's notice. (2) Division officers under the command of competent executives to personally direct the work and provided with a force of intelligent workers sufficient in number to cover the division fully at least once a week. (3) A school of instruction in detail work of mosquito destruction. (4) All employees should be trained to act in squads of three or four, and the proportion of untrained to trained men in any squad should, so far as possible, be held down to one in three, and in this kind of work more than in any other known to me, the master's hand must be ever on the helm. The division chief must be sleepless in his vigilance, for nothing short of absolute efficiency will attain, promptly, the end in view. The latter part of the paper elaborates the working details of such an organization.

The Differential Diagnosis Between Chronic and Recently Acquired Herniæ from a Medicolegal Standpoint.—H. J. Butte points out some of the distinguishing features between old and recent herniæ. These concern the shape and consistency of the sac, the pigmented appearance of the hernial surface in the older cases, the size and shape of the ring, reducibility, pressure, or absence of acute inflammation, size and shape of the inguinal canal, presence or absence of truss marks, the fact that when a truss has been worn for a long time the pubic hairs are matted down, curled up, or worn off to a considerable extent, due to mechanical pressure and function, the relaxed pouch in old scrotal herniæ the frequent failure of trusses to hold chronic herniæ in place, and the constitutional symptoms such as nausea, vomiting, etc., which often follow recently acquired herniæ, the result of traumatism. At the end of his paper he summarizes in parallel columns the respective features of recently acquired and chronic herniæ.

Journal of the American Medical Association, October 26, 1907.

Epidemic Acute Poliomyelitis in Norway.—F. Harbitz and O. Scheel gives an account of an epidemic of acute poliomyelitis occurring in Norway in the years 1903-6, with special reference to the nature and pathology of the disorder. In 1905-6 a total of 1,053 cases was reported, with 145 deaths, or 13.8 per cent. Both adults and children were affected, the latter chiefly. The mortality was high in some districts, very slight in others. While most of the cases were followed by the usual paralysis, some were very mild and otherwise atypical,

but the morbid process was probably the same. There was some evidence pointing to contagion in some cases, and the disease seemed to leave a certain immunity. The authors have had opportunity to examine necropsy material from nineteen cases. Aside from the central nervous system, the findings were in all essentials negative. As regards the nervous system, they summarize their conclusions as follows: "In a severe or fatal case of acute poliomyelitis we, as a rule, have before us a diffuse inflammation of the entire cord with its pia mater, of the entire medulla oblongata and pons, of the basal ganglia and often also of the cortex of the brain to a greater or less extent, always in connection with a similar inflammation in the pia mater." They examined also four milder cases in which the patients had died of complications during the stage of repair; and in these cases by the use of special methods they were able to demonstrate the existence of degenerated conditions in the central nervous system greater than they had expected to find. The common character of the pathological process in cases clinically resembling Landry's paralysis, bulbar paralysis, and localized myelitis was also made evident in their examinations. As regards multiple neuritis in these cases their findings were negative, only what must be regarded as secondary changes being found in the peripheral nerves. A case of what was clinically meningoencephalitis occurring with this epidemic showed similar pathological anatomic conditions. Their investigations furnished no evidence of any relationship between this disease and cerebrospinal meningitis. They consider that there is no question but that acute poliomyelitis is an infectious disease dependent on a specific microorganism. This is true at least of the epidemic cases. The diplococcus described by Giersvold was found in the cerebrospinal fluid in three of their cases, but was lacking in the majority. While they cannot speak definitely as to its specificity, they think it demands further investigation. It is evidently an organism difficult to demonstrate; it seems to die rapidly, and experience shows that microorganisms soon disappear in the nervous system. It is their belief that poliomyelitis is due to the direct action of some germ, and many facts favor the assumption that the atrium of infection is in the digestive tract, the nervous system becoming involved through the lymph stream along vessels and nerve trunks or through the blood.

Scarlatina and Dukes' Disease.—A. C. Cotton notices the slowness of acceptance of Dukes' disease as a clinical entity by the medical profession. While all admit the occurrence of cases hard to place and of too frequent apparent exceptions to the law of immunity governing the contagious exanthemata, the skeptics insist that the clinical evidence is yet insufficient to prove the real existence of the fourth disease. Cotton gives a summary of the symptoms of Dukes' disease as he understands it. It is differentiated from scarlatina by: 1, Long period of incubation; 2, absence of initial vomiting; 3, moderate fever of brief duration; 4, normal ratio of pulse to temperature; 5, absence of characteristic scarlatinal tongue; 6, the absence of, or if present, the fine character of desquamation; 7, the freedom of sequelæ; 8, probably the absence of leucocytosis. When one or more cases of apparent mild scarlet fever occur in a family giving a clear history of former attacks of scarlet fever, Dukes' disease may be suspected. There were but few cases of rubella, as we understand that disease. Cotton is confident that the health department reports represent less than one-fourth of the epidemic. Twenty-four physicians personally interviewed admitted having had 478 cases, though reporting only 117, the others being diagnosable only as suspicious.

Medical Treatment of Cholelithiasis.—G. Dock says that two things have contributed to put the treatment of cholelithiasis on a certain basis: First, Naunyn's demonstration that gallstones are chiefly due to infection and stagnation of bile, supplemented by Kramer's experiments showing that the colon and typhoid bacilli precipitate bile in the test tube, and, second, the revelations of the actual conditions by surgeons. Preventive measures consist in regular healthful habits as to diet, regulation of the bowels, moderate exercise, avoidance of tight clothing and anything that can cause congestion of the portal circulation. Systematic deep breathing is perhaps useful in overcoming such congestions. Among drugs, salicylates are probably of definite value as disinfectants and cholagogues, but they should be watched and stopped if undesirable effects appear. The presence of the stone is less important than the existence of the infection, and the therapeutic problem is not to lessen pain so much as to lessen inflammation and the attendant risks. The majority of the cases, in the attack, are not surgical, but they should be viewed with a surgical eye, and if the physician is unable to do this he should have a surgeon's cooperation. For the attack, anodynes to relieve pain, but not entirely to becloud the clinical picture, are advised. Local hot applications and the hot full bath are useful, but copious washing of the stomach with hot water or hot Carlsbad water is better. Rest so far as possible and movements of the bowels should be encouraged. The after-treatment depends on the suspected conditions in the biliary tract, and after the acute symptoms have passed especial attention should be given to the occurrence of bile in the urine or stools, leucocytosis, etc. The passage of gallstones out through the common duct is a comparatively rare event and in many cases in which this is supposed to have been the case perforation has actually occurred. Perforation can easily happen in the severer attacks of bilious colic, but it sometimes occurs with symptoms so mild as to be overlooked at the time and only discovered by operation or autopsy. Olive oil may possibly be of some service in reducing gastric hyperacidity and hypermotility, thus improving intestinal digestion and relieving some of the symptoms.

Congenital Squint.—W. C. Posey remarks that it is doubtful whether or not a distinct discrimination is always made between congenital and concomitant squint. The usual diagnostic point of difference, the limitation of the movements of an eye, is not always easily detected in young children, and when seen may be referred to a postnatal cause. It is only after the visual centers begin to be educated that the flaw in the mechanism becomes manifest, moreover, actual paralysis may not appear until the demand on the defective cerebral center has begun to impair its function. There are, however, other signs that can aid the diagnosis, and among these he mentions the inequality of the primary and secondary deviations, the absence of involvement of the iris and ciliary body in congenital palsies, and the reaction of degeneration in the levator in acquired cases in which ptosis is present, the detection of nystagmus in congenital squint, etc. The centers, or peripheral, as in case of muscular abnormality or orbital malformation. Heredity plays a large part, and the defect is especially frequent in Jews. The types of deviation in congenital squint are manifold, as is shown in seventy cases briefly reported in the paper. A not uncommon type is divergence of the visual axes, and there is frequently an anatomic basis in divergent orbits or some abnormality of muscular insertion. A summary of the types in the seventy cases is given, and the author insists on the importance of the early recognition of this abnormality, not only on account of the ocular defect, but also because of its significance as a symptom of possible obscure central nervous defect. The treatment is necessarily quite different from that of concomitant squint, no orthoptic exercises are of any use, operation is the only recourse, and this often presents great difficulties. The case should be studied in every detail and the ordinary rules may have to be abandoned. A single operation is seldom sufficient, tenotomy of one or more muscles and advancement of associates will usually have to be performed. The article is fully illustrated.

The Lancet, October 12, 1907.

Vincent's Angina Involving the Larynx and Trachea.—H. W. Bruce reports the case of a man of 47 years with a purpuric rash, mainly on the lower extremities for some five days, with a bloody diarrhea. He did not complain of his throat, but on the day after admission to hospital his respiration suddenly became obstructed and a laryngotomy was necessary. Subsequent examination of the throat revealed a sloughing uvula and a soft palate typical of Vincent's angina. Culture tests confirmed the diagnosis. The laryngotomy tube was retained for four days. Meanwhile there was considerable cough and expectoration and a very foul discharge from the tube. The tissues of the neck about the wound became swollen and indurated and in two or three days began to slough. A gangrenous process spread downwards and outwards on both sides of the neck, on the left side as low as the clavicle. It then stopped spreading and a sharp line of demarcation from the neighboring tissues began to form. Signs of pulmonary involvement soon appeared and the man died in a septic condition on the eleventh day. Autopsy showed the uvula nearly separated by the sloughing process. The lateral edges of the epiglottis and the edges of the ary-epiglottic folds were covered with a superficial green slough. The laryngeal mucosa below the false cords and of the trachea nearly down to the

bifurcation were in the same condition. Several of the tracheal rings were bound by the same necrotic process. A diffuse bronchopneumonia was found in the lungs. The lesions in general resembled those of hospital gangrene. The process in the neck was doubtless secondary to that in the respiratory tract and resulted in direct infection of the laryngotomy wound by the laryngeal and trachial discharges.

Fatal Case of Angioneurotic Edema.—The patient of H. Bazett was a poorly nourished man of 33 years who was found dead from suffocation on the physician's arrival. It was learned that he had had scarlatina at the age of six years and had thereafter been subject to frequent attacks of violent abdominal colic, lasting sometimes for nearly 24 hours. Associated with them, though never apparently synchronous, occurred sudden swellings of various parts of the body—hands, thighs, and scrotum. These swellings were apparently induced by slight injuries or chills. In childhood they had attacked the face and throat but never since. No medicine had been of any avail. In the final attack swelling began after the skillful extraction of a bicuspid tooth with an apparently healthy gum. In twelve hours the cheek began to swell on that side, the swelling extending over the face and eyelids. Toward night of the same day the neck began to swell and then the throat. During that same night he awoke choking, sprang up, and tried to clear his throat with his finger, but died in the suffocating attack. A diagnosis of angioneurotic edema was made by the reporter and was concurred in by several physicians who saw the case. There was no family history pointing to any hereditary influence. Autopsy, 42 hours after death, showed some edema of the larynx on the ary-epiglottic folds. Immediately after death the structures around the faucial aperture were swollen and this swelling increased during the 24 hours succeeding death, but had nearly disappeared by the time the autopsy was made.

Influence of Diet on the Liver.—C. Watson details the results of two series of observations. One experiment consisted in feeding a large number of rats on an exclusive ox-flesh diet, this being essentially a mixed diet of protein and fats. In this experiment it was observed that the percentage weight of the liver in meat-fed rats was, as a rule, considerably greater than in the control bread-and-milk fed subjects, the difference being such as could not readily be explained by mere variation in the blood-supply of the organ. An objection may be raised that the use of an exclusive flesh diet is too unnatural a régime to allow any deductions to be drawn which can be applied to conditions obtaining in man. To meet this objection attention is therefore more particularly directed to the detailed results of a second series of observations, which consisted in comparing the percentage weight of liver tissue in wild rats living, it is assumed, on a highly nitrogenous dietary with those of an equal series of animals obtained chiefly from the same source which were fed on a diet of bread and milk in fixed proportions, a diet which contained a much smaller proportion of nitrogenous food. This diet of bread and milk is one which has been proved to be well adapted for the growth, general health, and fertility of the ordinary tame rat.

British Medical Journal, October 12, 1907.

What Can the Family Doctor Do for the Inebriate? J. S. Bolton would begin the treatment of alcoholism with a hypodermic dose of apomorphine, even if the patient is delirious. He will quiet down and go to sleep with perhaps antecedent vomiting. The next step is to determine whether the man wants to give up alcohol or simply to get straightened out. Patients cannot be cured against their will, but sometimes new hope may be put into them and they can be shown that a permanent cure is perfectly possible. Combinations of atropine and strychnine may now be used, also hypodermically, two or three times daily. For a stomachic capsicum and cinchona tinctures are recommended, preceded if necessary by a calomel purge. Albuminuria is no contraindication of the foregoing. In fact, the urine often clears up under the treatment. As the general condition improves the frequency of the injections should be lessened. Depression and despair pass away. The nerves are steadied and appetite returns. It is needless to say that such a treatment can be carried out only under strict regular medical supervision. The patient must be warned against overconfidence. If he becomes restless he should at once submit to a brief renewal of treatment. A relapse is not more difficult to treat than any original attack. Old, harmful associations must be broken up and the mind and body both occupied in useful work and healthy recreation.

Malignant Disease of the Cecum Rendering an Inguinal Hernia Irreducible.—The patient of C. T. Plowright was a man of 57 years, with an irreducible hernia of long standing in the left side and causing him considerable pain. On the right side was a reducible complete inguinal hernia. After a week of palliative treatment without result, the sac was opened and was found to contain a loop of large intestine markedly adherent to the sac. On freeing the gut a hard mass of malignant disease was found in the concavity of the loop, and in the center of this mass a small abscess cavity containing 2 or 3 drams of foul, appendix-abscess-like pus; this was evacuated, and the loop of intestine was excised, together with about 2½ inches of healthy gut on each side of the growth. The cut ends of the intestine were fixed in the original incision in the inguinal canal, an end-to-end anastomosis not being considered advisable, owing to the presence of the pus. The patient made an uneventful recovery. The colotomy opening so formed was only meant as a temporary measure, but the patient having been fitted with a double inguinal truss, the pad on the left side being replaced by a cup-shaped receiver for the feces, found that he could get about his work all day without any inconvenience and refused to have an end-to-end anastomosis done. One year after the operation he had gained weight, the colotomy wound was healthy and there was no evidence of secondary deposits in the liver. The mass removed represented one foot of large intestine with a growth involving the central six inches and at one point protruding into the hernia. The center of the growth contained a necrotic area. Diagnosis by the microscope was a columnar carcinoma.

Modification of Leishman's Method of Estimating the Opsonic Index.—H. B. Dodds after experiments with blood and citrated emulsion of tubercle bacilli, said the results showed marked discrepancies between the Wright and Leishman methods, a normal index working out, for instance, to 2.0 or to 0.5, and seldom exactly to 1.0. After trials in various directions it appeared that the inconstant factor vitiating results was the differing number of leucocytes in the respective bloods. Counts of the leucocytes, estimations of the index by Wright's and by Leishman's method modified, were then made, and it was found that the figures, expressing the index by Leishman's method and the number of leucocytes, varied inversely, the emulsion being constant. By a simple formula, based on the above proposition, several apparent indices were corrected, and were then found to agree closely with those estimated by Wright's method; but still discrepancies occurred, and for the following reason: It is usually convenient to obtain blood by the pressure of an elastic or other band; if the same drop of blood thus obtained is used both for the index and leucocyte count, good results are produced. But this needs agility, and in practice would require an assistant. If different drops of blood are used, the hemocytometer and incubation pipettes may contain differing numbers of leucocytes; it is inconvenient to get blood without pressure, as a deep puncture has then to be made, possibly daily. Finally, a simple plan was hit upon; after mixing blood direct from the finger—under any pressure, with the bacillary emulsion, the number of leucocytes in the mixture itself was counted, either before or after incubation, each batch being done in the same way. For this the red blood corpuscle pipette serves, and the process is more rapid if there is one for each blood; but any pipette and any dilution desired may be used by drawing up successive volumes of the mixture and diluent as recommended by Wright. After using a drop or two to make a film the mixture is kept in its capillary tube till required for the leucocyte count. The total number of leucocytes need not be estimated, the figure expressing the average for the fields sufficing. A fallacy exists that the phagocytes are not in constant proportion to the total number of leucocytes. The actual modification of Leishman's method is very simple. The capillary pipette is that in ordinary use; it is convenient to make a bend in it 2 to 3 inches from its distal end. A rubber tube, as in the hemocytometer pipette, is easier to manage than a rubber teat, or a Wright's throttled pipette may be used. A mark is made above the bend, giving a long column of blood and emulsion, making for greater accuracy of dilution and providing enough of the mixture for its two purposes—namely, for making a film and for leucocyte count. The emulsion consists of (tubercle) bacilli suspended in citrated normal saline—say, 0.75 per cent. each of sodium citrate and sodium chloride. This emulsion is sucked up to the mark above the bend; it will be found that it is difficult or impossible to do this with a rubber teat owing to fluidity of the emulsion (unless a throttled pipette be used). The pipette may now be laid down, and the column of emulsion will be found to stay steady while a puncture is made in the finger. A short column of air having been

taken up, a column of perfectly fresh uncoagulated blood is aspirated to the mark, and the whole rapidly blown out on to a glass slide, so that the citrate may at once act on the blood and so prevent coagulation; this is not so efficiently done if blood is taken up first. The two fluids are then mixed, aspirated, sealed, and incubated, unless a portion be reserved for the leucocyte count. The films are made in the usual way, by blowing out and mixing before spreading; this remixing is important if the estimation of the leucocytes is made after incubation. The film need not be fixed before staining with carbol fuchsin; the index is calculated in the usual way. To correct the apparent index, multiply the control index by its corresponding number of leucocytes and divide the result into the other index multiplied by its corresponding number of leucocytes.

Deutsche medizinische Wochenschrift, September 26 and October 3 and 10, 1907.

The Ocular Diagnosis of Typhoid Fever.—Chantemesse describes a method of obtaining an ocular reaction to typhoid toxin somewhat similar to the conjunctival reaction occurring in tuberculosis. To prepare the necessary reagent typhoid cultures are sterilized at 60° C., the bodies of the bacilli are dried in vacuo, and are then triturated for several hours in an agate mortar. The watery extract of the resulting powder is heated to 60° and the clear liquid is poured into an excess of absolute alcohol. The resulting precipitate is dried in vacuo, and to perform the test 8 to 10 mg. of the powder so obtained is dissolved in a cubic centimeter of water. One drop of this fluid is placed in the lower conjunctival sac of the patient and if the case is one of typhoid infection in a few hours a local reaction appears characterized by redness, a sensation of burning, lacrymation, and a small amount of fibrinous exudate. The intensity of the reaction is subject to the individual idiosyncrasies of the patients and to the amount of toxin applied. In persons not suffering from typhoid fever little or no reaction follows, whereas if the disease is present the local symptoms are very pronounced, and what is especially characteristic, persist for from one to three days. The author states that in 200 applications no unpleasant sequelæ resulted. In testing fifty nontyphoid patients no positive results were obtained, whereas in seventy cases of the disease the result was positive. In a number of instances the ocular reaction was obtained at an earlier stage of the disease than the agglutination reaction.

The Dissemination of Typhoid Fever by Bacilli Carriers.—Kossel says that it has been found that not only do persons who have once suffered from typhoid sometimes continue for a very long time to throw off bacilli in their stools, but even individuals who apparently have never had the disease but who have been in proximity to a typhoid fever patient may excrete the organisms in the feces or urine. This state of affairs apparently may go on for years so that these individuals may during whole decades or even their entire lives be a source of danger to their environment. The habitat of the organisms in these cases is supposed to be the gall-bladder which continually reinfects the intestinal contents. Kossel describes in detail several small epidemics of the disease apparently due to an individual of this description who was employed in a dairy supplying milk to the city in which the epidemics in question occurred.

Echinococcus of the Optic Nerve.— Papaioannou says that echinococcus is not at all uncommon in Greece owing to the fact that most of the peasants live in a manner that predisposes to the disease. Many of them are shepherds who live in close association with their dogs, and the wells and springs that supply drinking water are also frequently sources of infection. According to the statistics gathered by the author, 72.4 per cent. of echinococcus cases in Greece affect the liver, 3.4 per cent. the spleen, 2.5 per cent. the kidney, 7.7 per cent. the peritoneum, 4.7 per cent. the lung, 1.2 per cent. the breast, .8 per cent. the orbit, 1.2 per cent. the bones, 4.7 per cent. the muscles, .4 per cent. the thyroid, and 4 per cent. the broad ligament. He describes several cases of the disease, in particular one in which the optic nerve was the seat of the cyst formation. The patient was a boy of twelve years, who six years previously had developed severe pain in the right eye, which for a time was the seat of an inflammatory condition. Vision failed rapidly and disappeared completely at the expiration of a month. On coming under the author's observation there was a pronounced exophthalmos and the pain had recommenced. The diagnosis of malignant new growth was made, but while evacuating the orbital contents the cyst burst and its true nature became apparent.

Cutaneous Inoculation with Tuberculin in Adults.—Bandler and Kreibich describe observations made on adults to determine the effectiveness of Pirquet's method of cutaneous inoculation with tuberculin. Pirquet's direction for children was to use old tuberculin diluted four times, but as the authors were dealing with adults they employed the reagent in concentrated form. The inoculation was performed by applying two to three drops of the tuberculin to the skin of the arm or the back, and then scarifying the spot by means of a lancet. The same scarification was carried out in another spot as a control without the introduction of the tuberculin. Out of thirty-seven cases in which no manifest tuberculosis existed fifteen patients gave no reaction at all at the first inoculation. On repetition of the test in two cases a weak reaction was observed. Of the remaining thirty-two cases ten gave a weak or undeterminate reaction and the other twelve gave a distinctly positive result, manifesting itself in the form of swelling and redness at the site of scarification. Another series of patients comprised individuals suffering from local cutaneous tuberculosis; out of twenty-six such cases in twenty-two a strongly positive reaction was obtained; the other four were cases of advanced miliary tuberculosis which did not give any reaction on inoculation or on the injection of tuberculin. The unresponsiveness of such patients to tuberculin has already been pointed out by various observers. The microscopic structure of the lesions produced at the site of inoculation is also described.

The Resection of Large Nerve Trunks Without Paralysis.—Roeder says that a number of instances have been reported in which the resection of peripheral nerve trunks has not been followed by the usual sequelæ. As cases of this sort are still very rare, it is advisable to collect all the evidence possible bearing on the subject. So far there is no satisfactory explanation of the occurrence. It has been suggested that, somewhat as is the case with the blood-vessels, collaterals may form and take up the function of divided nerves. Goldman believes that in cases in which the continuity of the nerves has been destroyed by neuromas, the damage to the nerve was congenital and was compensated for during intrauterine life by the development of new branches bridging the gap due to the neoplasm. In the author's own case two neuromas were removed from the upper arm and shoulder of a young woman. In order to extirpate the tumor in the former situation it was necessary to resect a portion of the ulnar nerve with which it was intimately related. It was expected that paralysis would follow, and the distal end of the nerve was grafted into the median nerve trunk, but the next day on removing the dressing it was found that the patient had perfect control of the extremity. A year later another similar but much larger growth was removed from the pelvis and in doing so the anterior crural nerve had to be sacrificed. Here again no impairment of function followed and the patient while recovering from the anesthetic moved the member in all directions. A similar observation was made in connection with the removal of a smaller growth in the neck, involving the spinal accessory nerve.

Percussion in the Treatment of Pseudarthroses.—Schäffer recommends that in cases of delayed union after fractures, owing to deficient callus formation, the bone in the neighborhood of the break be subjected to forcible percussion with the ulnar edge, of one or both hands. The blows must be more vigorous than those ordinarily employed in massage, since the intention is to induce a periostitis and so stimulate the processes of repair. In one instance in which the procedure was tried together with massage and the application of a removable dressing of water glass new union after fracture of the tibia four months previously was rendered firm in about six weeks and bony union resulted. In another similar case of eight months' duration the results were equally satisfactory, and the author thinks that the advantage that immobilization of the limb is not required during the treatment is a great point of superiority over the usual operative measures. In the first one of the author's cases the injection of blood was to have been tried and in the other wiring of the bone ends was contemplated, but these measures were rendered unnecessary in each instance. It is stated that the patients did not object to the procedure.

Sydenham Society.—News comes of the probable end of the new Sydenham Society of London, Eng., which for many years has been a publication society of leading medical men of Britain. The revenues and literary attention of the society have been given almost exclusively to translations of French, German, and Italian monographs of high character, and to richly illustrated atlases, all of which are very nice to have in one's library, but are too elaborate and expensive for practical, everyday purposes.—*Clinical Review.*

Book Reviews.

Alcohol, the Sanction for Its Use. Scientifically Established and Popularly Expounded by a Physiologist. Translated from the German of Dr. J. Starke. New York and London: G. P. Putnam's Sons, 1907.

The title of this volume is an adequate indication of its contents. The book is divided into two main parts called, respectively, Medical and Physical; and each of these consists of several chapters. The volume commences with a very useful chapter containing an epitome of the chief conclusions reached in the discussion. From this chapter we extract the following, as referring to the medical aspect of the subject: "The alcohol of alcoholic drinks does *not* of itself possess the property of inducing persons to take ever-increasing amounts. Furthermore, it is easy for any healthy person to restrict his use of alcohol within the bounds of moderation. As a rule a person comes to know well enough the amount of alcoholic drinks which is wholesome for him; therefore everybody is perfectly well aware of what is moderate and what is not. . . . 2. The moderate use of alcohol has nothing to do with drunkenness. . . . 3. The moderate use of alcohol has nothing to do with the development of any disease whatever. . . . 4. The moderate use of alcohol is for many a man of the present day a very important hygienic measure. . . . 5. The fact that the physician often interdicts alcoholic drinks in a few diseases, restricted in number and more or less severe, does not militate against the moderate use of alcohol by the public, since the same is the case with regard to other articles of food and drink which are generally harmless." The book is one that should be read by all interested in this subject, whatever their preconceived views may be; there is much in it that is of interest, and much that is likely to provoke controversy. It will serve a purpose as an antidote to some of the modern publications on the subject in which philanthropic or partisan views and assertions are more noticeable than scientific facts and reasoning.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. Edited by W. T. Longcope, M.D., Philadelphia. Vols. I and II, Seventeenth Series, 1907. Philadelphia and London: J. B. Lippincott Company, 1907.

The first two volumes of the Seventeenth Series of International Clinics do not differ materially in any respect from their predecessors, and the high excellence of the contributions continues without change. The opening article of Vol. I by L. F. Barker of Johns Hopkins is on the psychic treatment of functional neurosis. The topic is treated with the lucidity and literary finesse which are characteristic of Professor Barker. Among the other contributions we notice, as one embodying patient original research, the essay of G. W. Norris of Philadelphia on the Functional Capacity of the Heart. The author employed Katzenstein's method of investigating the functional capacity of the heart in a number of patients. An article by Theodore Diller of Pittsburg on Exhaustion and Toxemia as Underlying Factors in the Production of Neurasthenia presents the etiology of neurasthenia, hysteria, and deliriant states from the viewpoint of modern theories, and the cases reported certainly seem to offer evidence of the probable correctness of the hypothesis. An interesting article by Tuffier of Paris presents the latest experimental work in operations on the thorax in pneumatic chambers. He prefers the Brauer apparatus, but suggests for the purpose of preventing infection as well as reducing the amplitude and number of respirations the administration of air surcharged with oxygen during the operation. Dr. Hudson Makuen contributes an article on Hysterical Deaf Mutism, which very clearly and concisely develops the points of interest to practitioners in this condition. In the second volume is a still more varied array of valuable contributions on therapeutics, medicine, surgery, gynecology, pediatrics, neurology, and pathology. A brief article by R. J. Cole of Johns Hopkins on the Vaccine Treatment of Infectious Diseases will interest those who are working along the lines laid down by Sir A. E. Wright. Dr. J. M. Taylor of Philadelphia contributes a very practical and authoritatively written essay on The Management of Exhaustive States in Men, in which he describes among others Muldoon's famous system recently applied to a statesman of national fame. An excellent and very concise article on the detection of the ova of intestinal parasites in the feces by Maurice Latulle of Paris gives all that the practitioner needs to know on this subject, while that of F. P. Rous of Michigan gives a résumé of the examination of the cerebrospinal fluid. A plea for local anesthesia in operations for inguinal hernia by J. A. Bodine of New York offers much food for reflection, as it is based on a very large experience—428 operations. The gem of the collection, from the practitioner's viewpoint, is the article of Dr. J. B. De Lee of Chicago on Postpartum Hemorrhage and Its Treatment. C. D. Palmer's article on Dysmenorrhea and Its Treatment is also of practical value and replete with suggestions. These articles are merely mentioned as particularly of interest to the practitioner. The volume, however, contains much other valuable material which limited space forbids us to discuss.

A Manual of Treatment of the Diseases of Children. By W. F. Radue, M.D. Chicago: The Clinic Publishing Company, 1907.

The purpose of this book is explained by the author in the preface: "This little work was undertaken to explain, as briefly as possible, the dosimetric or alkaloidal treatment of the diseases of children; with a short description of each disease, and the usual doses of the various medicines used." No one, therefore, will mistake this volume for a work on pediatrics. Within its special therapeutic limitations it seems to be a useful book.

Modern Medicine. Its Theory and Practice in Original Contributions by American and Foreign Authors. Edited by William Osler, M.D., Regius Professor of Medicine in Oxford University, England; Honorary Professor of Medicine in the Johns Hopkins University, Baltimore; Formerly Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and of the Institutes of Medicine in McGill University, Montreal, Canada. Assisted by Thomas McCrae, M.D., Associate Professor of Medicine and Clinical Therapeutics in the Johns Hopkins University, Baltimore. Volume II. Infectious Diseases. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1907.

The first fifty pages of the second volume of this system are devoted to an extremely readable article by Dr. Ludwig Hektoen on the general nature of the infectious diseases. This serves as an introduction to the succeeding chapters on the separate maladies, and gives a very lucid critical survey of the somewhat inchoate mass of material bearing on this subject that has accumulated during recent years. The succeeding five chapters on typhoid fever by Dr. McCrae form an interesting monograph, in which the discussion of the sociological and prophylactic problems is commendable. The complications are also described with unusual fullness and it is gratifying, in a work edited by Osler, to find over twenty pages on the subject of treatment alone. Hydrotherapy materially receives consideration at much length, and in this connection it is interesting to note the sharp distinction drawn by the author between the effect of tub baths and of the packs or sponges that are often resorted to as a substitute for the former. The tub bath is said to be quite different in results from the less active measures and actually modifies the course of the disease and wards off complications; whereas the use of packs and sponges is only symptomatic. The next two chapters on typhus and relapsing fevers are also by Dr. McCrae. Dr. W. T. Councilman contributes the article on smallpox, which includes an interesting review of the investigations on the causative agent of the disease carried out by the author and his coworkers. Vaccination is discussed by Dr. George Dock, and the next chapter on chickenpox is also by Dr. W. T. Councilman (though his initials appear here as W. F.). In the article on scarlet fever by Dr. John H. McCollom the view is expressed that the protozoon-like bodies described by Mallory in the skin of patients suffering from the disease are probably not degeneration products, but are protozoa and have an etiological relation to scarlet fever. Measles, rubella, the fourth disease, erythema infectiosum, whooping cough, and mumps have been allotted to Dr. John Ruhräh and diphtheria to Dr. McCollom. Influenza and dengue are written of by Drs. F. T. Lord and T. D. Coleman, respectively, and thirty pages on meningitis have been contributed by Dr. Henry Koplik. The chapter on erysipelas is by Dr. James M. Anders, and Drs. John H. Musser and George W. Norris are the joint authors of the three chapters on lobar pneumonia, covering 110 pages. Aerotherapy as advocated by Northrup is recommended for this disease and hydrotherapeutic measures are stated to deserve more confidence than other forms of local treatment, especially jackets and poultices, the use of which is deprecated. The chapters on toxemia, septicemia, and pyemia are the work of Dr. Richard M. Pearce, and that of acute rheumatism is by Dr. Frederick J. Poynton. Asiatic cholera is treated of by Dr. W. P. Dunbar, and the late Dr. Jas. Carroll has contributed an authoritative chapter on yellow fever. The volume closes with chapters on plague and bacillary dysentery, written by Drs. W. J. Calvert and K. Shiga, respectively.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Thirty-fifth Annual Meeting, Held at Atlantic City, N. J., September 30, October 1, 2, 3, and 4, 1907.

DR. DOMINGO ORVANANOA OF MEXICO, PRESIDENT, IN THE CHAIR.

The Outlook for a General System of Registration of Vital Statistics.—Dr. CRESSY L. WILBUR, Chief Statistician, Bureau of the Census, Washington, contributed a paper on this subject. The author presented a map showing the extent of the registration area in 1895 and 1907. In 1895 there were only eight registration States for deaths. In 1907 there were fifteen registration States for deaths. There were no registration States for births in 1895, and even in 1907 the registration area for births was represented by only a few interrogation marks on such States as Massachusetts, Pennsylvania, and Michigan, indicating their possible addition within a short time, owing to the operation or effective enforcement of recent legislation. Study was made of the conditions of population, as density, literacy, etc., affecting the extension of the registration area, and of the favorable and unfavorable circumstances relative to the adoption of effective laws. It was estimated that in the light of experience of slow progress in the past, the United States could hardly expect to have a satisfactory system of registration of vital statistics, including both births and deaths and covering the entire country, much before the middle of the present century, at which time, if all of the present agencies now effectively cooperating shall accomplish this result, the nation will have reached a place of advancement in this respect that would be quite equal to that occupied at the present day by Japan. A standard certificate of death had been prepared by the Association and the Bureau of the Census, and extensively employed with resulting advantage in causing uniformity of the data collected; yet many States and cities had continued to employ their old forms, whose variety was multitudinous, and offices that had adopted the standard blank had not hesitated to materially change it, so that the information obtained was frequently entirely different from what it purported to be when returned to the Bureau of the Census upon the actual standard blank. The amazing thing about the way in which many deaths from tuberculosis were reported, as abscess of the chest, brain fever, marasmus, etc., was the general indifference of registration officials to the necessity of securing accurate statements of causes of death. Finally, he said if the people of the United States wanted a thorough system of registration of vital statistics they could get it. It would not be necessary to wait fifty or sixty years for the slow adoption and enforcement of adequate laws. The process could be hastened, and without departing from the constitutional requirement that the primary control of registration should be by the States, and not by the federal government. If Congress, if the people of the United States were really interested in this matter, and were determined that this thing should be done, the States would readily be brought into line.

Dr. JOHN N. HURTY of Indianapolis emphasized the importance of accurate registration of vital statistics. They had been trying to collect accurate statistics of deaths in Indiana, and now they were getting over ninety-five per cent. of deaths recorded, while the United States Census Bureau required but ninety per cent. The medical profession, as represented by the Indiana State Medical Society, had done everything it could, while individually the members of the medical profession at large had not come forward and assisted in this work. They had, however, been compelled to do so and give the records of death. Indiana was now prepared to give a complete registration of births. The law was behind the State Board, imposing a severe penalty for not recording births and deaths. If a dead body was buried in Indiana without a permit, and that permit was not issued until a certificate of death was returned complete, the Coroner disinterred the body and required the necessary data on the death certificate. They had a special police officer whose income was dependent upon fees, and he was continually on the watch for instances of illegal burial. According to the law births shall be recorded within twenty days after their occurrence. They had asked the legislature to make it immediate. The penalty of not reporting a death was, for the first offense, a fine of from ten to fifty dollars; for the second, a fine of fifty to one hundred dollars, and for the third, one hundred dollars. They had a clause in the latter stricken out at the last minute when the bill was on its final passage, namely, that upon a third conviction of the violation of this law for failure to report deaths or births a physician shall lose his license to practice in that State. This clause was stricken out by a lawyer, and not by a doctor, as the clause was approved by the Indiana State Medical Society.

Dr. QUITMAN KOHNKE of Covington, La., suggested to the officials of the Census Bureau that a uniform system of laws be submitted to each State for adoption. Law was the main reason why mortality statistics were not the same in every State. He hoped the Census Bureau would assist the whole country in getting a uniform system of laws to make the statistics of one State comparable to those of another.

Dr. HENRY MITCHELL of Asbury Park, N. J., said that in an experience of about fourteen years in New Jersey they had found that it was not a question of law, but one of enforcement of the law.

Sources of Error in the Laboratory Diagnosis of Diphtheria.—Dr. HIBBERT W. HILL of Minneapolis submitted what was actual proof and what must be assumed to make a bacteriological diagnosis of diphtheria logical and a practical success. First, the finding of diphtheria bacilli in a culture taken by itself proved nothing except their presence in the culture. Granting that the culture was properly taken, the finding of bacilli proved their presence in the throat, etc., from which the culture was taken, nothing more. Third, the presence of diphtheria bacilli in the throat plus appropriate symptoms justified the assumption that the patient had the disease, the evidence being that from 98 to 99 per cent. of all patients showing this condition had the disease. Fourth, the presence of diphtheria bacilli in the throat, without symptoms, required further data as to exposure. If a clear history of the absence of exposure could be obtained, it was legitimate to assume that the diphtheria bacilli found were likely to be non-virulent, the evidence being that eighty per cent. of such cases were not virulent. If exposure was established, a legitimate assumption was that diphtheria bacilli were virulent, and therefore, when present, might infect others who would come down with the disease in a short time, the evidence being that the infection obtained from a clinical case was almost invariable. Fifth, failure to find diphtheria bacilli in a culture was about 90 per cent. conclusive of their absence in the throat. If a second culture were taken, and also proved negative, the two consecutive negatives taken together afforded about 99 per cent. conclusive evidence. If two or three or four negatives were obtained, the absence of diphtheria bacilli was established with direct finality.

Dr. JOHN N. HURTY asked whether it was not possible that a non-virulent diphtheria bacillus in one throat might become virulent in another. For instance, the health officer might visit a school and find two or three cases of virulent diphtheria, and yet if cultures were taken from the throat of every child in the room, diphtheria bacilli would be found, but as these were making a good

defense against the disease, it was assumed that the bacilli were non-virulent. In Indiana they had been acting on the assumption that the bacilli were virulent when found in these children's throats. When found, action was taken immediately. If one went into a family to see a case of diphtheria it was clinical diphtheria or laboratory diphtheria, and whichever it was, antitoxin should be used on all children in the household, giving them immunizing doses. He had used antitoxin liberally whenever diphtheria existed, and felt that in several instances in his State he had stopped epidemics of the disease. For instance, in one county he rode twenty-seven miles, and in that time visited sixteen families, finding six cases of diphtheria. He immunized every child in each family, and this was the end of the diphtheria, in that there was no further spread of the disease. They did not inquire as to whether the children were infected with virulent or non-virulent diphtheria bacilli, and he believed this was good practice to recommend.

Dr. William C. Woodward of Washington, D. C., called attention to the distinction that existed between medical diphtheria and legal diphtheria. A year or two ago the question arouse in the District of Columbia as to the exact status of a child in whose throat or nose diphtheria had been found, but who showed no clinical symptoms of the disease, and a wise corporation counsel decided that if diphtheria bacilli were found in a man's or child's nose or throat that that man or child had diphtheria. The question of the presence or the absence of the clinical symptoms counted for nothing in law, and a man or child was a danger to the community who had diphtheria, and should be treated as such. Whether that was going to hold in the case of diphtheria patients he did not know.

Dr. B. Franklin Royer of Philadelphia was much impressed with the statement of Dr. Woodward as to what constituted legal diphtheria, and yet the speaker questioned if in a court of law one could prove legal diphtheria by finding the bacillus in accordance with bacteriological methods in the throat or nose cultures. These methods at present were snapshot, were not satisfactory to clinicians, nor to bacteriologists. The great trouble was that so many organisms were met with which closely resembled the diphtheria bacillus it was with great difficulty it could be positively excluded. Those who dealt largely with bacteriology agreed that a negative test of virulence with a culture that had been injected into a guinea pig was the only reliable test which would exclude some of the forms of diphtheroid organisms, and the simple presence of an organism pronounced by a bacteriologist from his routine culture methods, such as were used in public health work, was not sufficient evidence. A positive report that such an organism as the diphtheria bacillus was present would not be accepted in a court of law, if someone questioned whether it was a virulent organism or the true diphtheria bacillus. If its virulence had been tested, and it killed a guinea pig with typical lesions, it would be accepted.

Dr. Charles V. Chapin of Providence, R. I., said that as a health officer he undertook to restrain a boy who had diphtheria bacilli in his throat from mingling with other children, but he was not sick, and the court decided that he did not have diphtheria. Disease was one thing, but infection with disease germs was another thing. He felt very sure that the courts would interpret the term disease as applying to a pathological condition of the human body. They would not apply the term disease to a condition in which there was the presence simply of the organisms which might cause disease, and when, for some reason or other, they did not cause disease.

Dr. J. J. Kinyoun of Florida said a great many health officers and the majority of physicians placed too much stress on positive tests or preliminary cultures. He thought that just as soon as they attached less importance to preliminary tests and more importance to discharge tests, the better it would be for patients. In other words, the free use of antitoxin would cure more cases of diphtheria and render the office of health officer less difficult. As to what constituted diphtheria legally, he felt that the judge who rendered the decision referred to by Dr. Chapin was wrong, because if that generaly held, health officers would have to abandon practically all quarantine measures.

Dr. William Bailey of Louisville said he did not appreciate fully the close distinction that was made between legal and non-legal diphtheria. Whatever might be the judgment of a court, he thought that any child who had the bacillus of diphtheria in his throat ought to be put under control. He would not like a child of his to mingle with such a child, and even if it could be decided technically that in a given case the bacilus was non-virulent, it might become virulent. On the same principle one might take a rag or cloth that had come in contact with a smallpox patient into court, and while the court would not decide perhaps that the rag had smallpox and could not be convicted, yet he thought it was wise to take care of the rag the same as he would a child who had the bacilli of diphtheria in his throat.

Dr. Charles A. Hodgetts of Toronto, Ontario, mentioned an industrial school in Ontario of 250 scholars, in which for two or three years, now and then, there were true cases of diphtheria which were isolated. Of this number over fifty per cent. of the pupils were found to be the carriers of diphtheria bacilli. Those found to be sick were given immunizing doses of antitoxin and were segregated. The school teachers and children, however, grew tired of this segregation, and very soon the children were allowed to mix with one another. It would not surprise him if at any time cases of diphtheria were reported from that school. These cases should be dealt with in a rigid manner.

Dr. Hill, in closing the discussion, said it was necessary to take action as soon as possible whenever the existence of diphtheria was suspected among school children.

Control of So-Called Minor Infectious Diseases.—Papers were read on this subject by Drs. A. G. Young of Maine and Alfonso Pruneda of Mexico City, in which the authors discussed measures for controlling whooping-cough, measles, etc.

Dr. Gardner T. Swarts of Providence, R. I., said there was nothing more annoying than a lack of control of the minor infectious diseases. Health officers and physicians could not impress upon the public too strongly the importance of controlling measles and whooping-cough, for as long as these diseases were treated with indifference both by physicians and the people so long would they continue to spread contagion. Even though they could not be altogether prevented, they could be checked in a measure. The sooner physicians impressed upon school authorities and teachers that these minor diseases were dangerous to the public health, and laws and ordinances were enacted to that effect, the better it would be for mankind.

Dr. Quitman Kohnke said the importance of the so-called minor infectious diseases depended on locality, environment and climatic condition. Each locality should be guided by the local importance of any particular disease, and should adopt such measures as were justified.

Typhoid Fever at Knoxville, Tenn., and Its Relation to the Water Supply.—Messrs. Robert S. Weston and Ralph C. Tarbett of Boston contributed a joint paper on this subject. The evidence was against the supposition that the water supply was a cause of the high death rate from typhoid fever at Knoxville. The writers maintained that if the geographical distribution of each case for two or three years could be studied as it occurred, the causes of the disease would be shown and the remedy would suggest itself. Their studies show the importance

of paying more attention to the hygiene of the household independently of the great problems of public water supply and sewerage. Undisinfected typhoid excreta and other infectious material which could become insect borne should be destroyed, and typhoid patients should be forced by education and law to protect their neighbors against infectious disease.

Dr. Quitman Kohnke said that his experience in New Orleans bore out the opinion that typhoid fever there was in at least ninety per cent. of the cases brought from other places, notably summer resorts. Typhoid fever should be considered important wherever it occurred, and it would be competent in his opinion for the Association to issue recommendations based upon those facts.

Dr. John A. Macdonald of Brandon, Manitoba, said that typhoid fever had been prevalent in Brandon and thereabouts for twenty-four years, every fall. Sometimes it would come on in August and run its course in epidemic form for two or three months. One thing very noticeable this year was the absolute absence of flies until about six weeks ago. It is a curious coincidence, if such it might be termed, that typhoid was absent until the flies appeared. During the greater part of the summer very few flies were seen and it seemed to him that this was a noticeable observation in connection with the possible dissemination of typhoid fever by flies.

Dr. Edward V. Hug of Lorain, Ohio, said that Lorain was one of the first cities to adopt the mechanical filtration method of dealing with water. For several years this city had no sewer system. This was prior to 1892, and during those years the death rate from typhoid was about 44 per 100,000 population. During the past two years, 1906 and 1907, so far the death rate had reached 34 per 100,000. But during these years the city had been building a new plant, with a capacity of six million gallons a day.

Dr. Hibbert W. Hill had seen outbreaks of typhoid fever beginning with the freezing of the water supply and terminating when the river, for instance, thawed. In a town in the Red River Valley, with a population of four thousand people, ten per cent. of the inhabitants had typhoid fever due to a polluted water supply. The epidemic began when the river was frozen, but ceased when the river had thawed out again.

Dr. Henry D. Pease of Albany, N. Y., corroborated what Dr. Hill had said with reference to winter epidemics of typhoid fever due to the pollution of water supplies. He mentioned five or six epidemics of typhoid fever that had occurred, some in small towns, and some in large ones, which followed the course that was mentioned.

Contact Infection.—Dr. Charles V. Chapin of Providence, R. I., said the valuable report on typhoid fever in our army during the Spanish war and the observations of the English in the Boer war indicated very clearly contact infection as the chief factor in camp typhoid. Jordan's report on typhoid fever in Winnipeg also laid great stress on this mode of infection, and many recent writers in Germany and America attached great importance to it. It was the author's opinion that the larger part of the typhoid fever in the United States to-day was caused in this way. Only a small part was due to infected water or milk, and still less to infected air. There was ample room for improvement in the management of contagious diseases. We must teach those who had the care of the sick not to waste so much time on the invisible dry and dead microorganisms of the air, but to use more soap and water on their hands. Better still, try not to infect the hands or clothes in the sickroom. There was a great deal of unnecessary handling of the patient and of infected articles by health officers, physicians, and nurses. By paying more attention to contact infection, isolation in the family and hospital would be easier and more successful.

Uncinariasis in Florida.—Dr. J. J. Kinyoun undertook an investigation of this disease to ascertain the prevalence of the infection and to see how far the average practitioner would be interested in such an investigation and eradication of the infection. He examined the children of two orphanages in Jacksonville. There were 39 cases of the disease in all. Careful examination of all the cases showed that the children were undeveloped and were of low mentality. He contended that the majority of cases were infected through the skin, and a few through the alimentary tract. Although the latter could not be altogether excluded, the avenues of infection were far less than that of the skin. He urged that a systematic study of the prevalence of the disease in the State be undertaken.

High Altitudes in Tuberculosis.—Professor Weinzirl of New Mexico said that his observations had led him to conclude that the great changes in the daily temperature observed at high altitudes acted as a stimulant on patients, and this was the main factor in the high dry climate cure of tuberculosis. That dryness, altitude, and sunlight were important mainly because they were instrumental in producing these great temperature variations, which insured cold nights and refreshing sleep, while the stimulation produced a better appetite, better digestion, and the assimilation of food, thus affording the consumptive strength for combating the disease.

Effect of Heating upon the Determination of Leucocytes in Milk.—Prof. H. L. Russell and Mr. Conrad Hoffman of Madison, Wis., contributed a joint paper on this subject. In the methods heretofore proposed for the determination of the cellular content of milk, an important factor influencing the accuracy of the determination had been overlooked. It was found that pasteurized milks almost invariably showed a higher cellular content than unheated milks. The authors found that the heating of the milk to 70° C. for fifteen minutes increased the cellular content from 1 to 30 per cent. above that of the unheated milk. This increase was found to be most marked between 60° and 70°, the temperature at which the fat globule clusters were broken up to form a more or less homogeneous emulsion. Many cellular elements were normally entangled in these clusters, and were liberated only when the latter were broken up. That these cells were so enmeshed was clearly shown by allowing whole milk to separate by gravity and then examining the cream and skimmed milk thus obtained. The cream showed a very high cellular content as contrasted with that of the skimmed milk. When milk was first heated, the number of cells found in the cream was materially diminished, and those in skimmed milk increased. It was evident that the cellular elements were carried up with the cream, and unless the milk was heated, a large number would be drawn off with the supernatant fluid, and thus escape enumeration. Examination of this fluid from unheated and heated samples gave much higher results for the former than the latter. Heating of the milk prior to centrifugalization permitted of increased accuracy, as was evidenced from a large series of duplicate determinations, which showed an average variation of only 2.7 per cent. It was accordingly deemed advisable to heat all milks prior to examination for leucocytes, high enough to destroy the fat globule clusters.

Determination of Intestinal Bacteria in Milk.—Dr. Daniel D. Jackson of Brooklyn, N. Y., said a demonstration of the value of the lactose bile medium for determining the presence of intestinal bacteria in water had led to its use in the determination of *Bacillus coli* in milk. The restraining action of the bile salts on growths of the numerous other species of bacteria in milk admitted of its use, whereas the Smith solution gave entirely unsatisfactory results for this purpose, due to overgrowths and to the production of gas by species other than *Bacillus coli*. Contrary to expectation, it was found that when other

species were present, the *Bacillus coli* did not increase in number in milk, but gradually decreased so that the extent of fecal contamination could be measured. The range was found to fall within the same dilution as in water analysis. A clean milk, or one that had been pasteurized, rarely gave the test for *Bacillus coli* in the 1-10 dilution. A carelessly handled milk would give the test in the 1 c.c. dilution. A contaminated milk would give positive tests in the 1-10, 1, and 10 c.c. dilutions.

Diphtheria Diagnosis.—Dr. B. R. Rickards of Boston referred to some of the factors which enter into the bacteriological diagnosis of diphtheria. The question of types on which a positive report should be given was discussed from both the standpoint of diagnosis and release, the question being raised that in some cases greater leeway should not be allowed in release cultures owing to the clinical evidence of the organism. The personal element still entered into diagnosis to a certain extent, but could and should be reduced as much as possible. It was better for the diagnostician to have no knowledge of the clinical data of a case until the bacteriological diagnosis was made, owing to the mental bias which might otherwise be produced. In testing diphtheria organisms for virulence, varying results in the virulence of organisms isolated from the same culture had been noted and further work along this line was very necessary. The writer believed that there should be greater uniformity in the various laboratories as to what forms should be considered as positive for diagnosis and release, and he emphasized the necessity of further experimental work on most of the points regarding the value of coordinating diphtheria diagnosis and diagnostic procedures in general, in order that it might be placed on a standard basis.

The Diagnosis of Rabies.—Dr. A. W. Williams of New York City said that three methods had been used in helping to establish the diagnosis of this disease. First, animal inoculations; second, sections for the presence of small-celled accumulations about the blood-vessels and ganglion cells; third, sections and smears for the presence of the so-called Negri bodies. The second method had fallen largely into disuse, because the histological changes upon which its value depended had been shown to be non-specific for rabies. The first method was used as a decisive test when results from the third method were doubtful. The results obtained from the use of the third method were as follows: (1) Negri bodies demonstrated, diagnosis rabies. (2) Negri bodies not demonstrated in fresh brains, diagnosis very probably not rabies. (3) Negri bodies not demonstrated in decomposing brains, diagnosis uncertain. (4) Suspicious bodies in fresh brains, diagnosis probably rabies. The demonstration of the Negri bodies by smears was the most rapid and efficient method so far published. Improved technique had lessened the number of suspicious or uncertain cases. He described the technique of the smear method at present in vogue in the research laboratories of the New York City Health Department.

Milk.—There was a symposium on this subject. Professor E. B. Voorhees of New Brunswick, N. J., said the public should realize that even at twelve cents good milk was the cheapest and best nourishment it was possible to buy. To produce pure milk at the present selling price in the big cities at a profit to the farmer was impossible. The most careless dairyman could not turn out even his inferior grade of milk for less than 4.7 cents a quart, while an average cost of production of five cents was the lowest practical rate. A very small additional expense in the price of milk was necessary to guarantee absolute purity and general quality of milk.

Professor C. B. Lane said that the majority of dairymen would prefer to sell only the best milk procurable, if the public would pay for it, and he declared that the general public was quite willing to stand the higher rate. More stringent legislation was needed to procure permanent results. At the present time the man who added water to the milk was fined. Generally, the man who sold impure milk went scott-free, and this despite the fact that the latter was much the greater menace. He advised national laws modeled after the British statutes which permit a consumer to sue for damages a dealer who supplies him with impure milk.

Dr. Thomas Darlington of New York advocated that each community should look after its own milk supply. He recommended systematic and constant inspection, in the first place, and, in the second, the prevention of the sale of any milk which was unwholesome and adulterated. Every dairy and every creamery supplying the city of New York had already been inspected. As for preventing the sale of unwholesome milk, he had only to mention that the Court of Special Sessions a day or two ago had 260 cases before it. Gastrointestinal diseases had been markedly reduced since the proper inspection of milk had been enforced.

Professor R. A. Pearson of Cornell University discussed the protection of milk under five headings, namely, health of the cow; cleanliness of the cow and her surroundings; condition of the utensils in which the milk was handled; cleanliness of the employees, including their health, and the cooling and storing of the milk. Speaking of the tuberculin test, he said that when farmers clearly understood its true value, they would want this test made. When they were shown by demonstration that which they failed to understand, they were anxious to have this test. Very many milk producers were honest and anxious to do what was right. They needed instruction. A campaign of education had been begun. It needed support. Every milk producer should have the opportunity to know the latest concerning his business, then many of them would make the desired improvements in their dairies, and the realization of ideal dairying would go hand in hand with the necessity of enforcing laws.

Social Ethics as Influenced by Immigration.—Dr. Peter H. Bryce of Ottawa, Canada, said that immigrants were pouring into the United States and Canada at the enormous rate of a million and a half annually, and it was a grave question whether this tremendous influx of human flotsam and jetsam would be assimilated or continue a foreign mass and a menace to the nation. Invasion of foreign labor had driven American girls from mills and factories to a higher plane of employment. But the standard of intelligence was too low for foreign competition seriously to affect American mechanics. The mental status of immigrants to-day was higher than that of many years ago. Steamship companies forced by close competition expended enormous sums in new ships, deliberately seeking the immigrant as a means of making up their losses. This was one of the evils of the problem with which America and Canada had to contend.

The Mexican delegates reported that their country was constantly raising the barriers against undesirable immigrants, and urged that the United States Government at Washington formulate a new code of laws that might be adopted also by Canada and Mexico.

Trachoma and Immigration.—Dr. Augustin Chacon of Mexico City said that immigrants to that Republic had been the cause of an epidemic of this disease of such serious proportions that it would be absolutely necessary for the government to adopt radical measures for the protection of the country.

Ophthalmia Neonatorum.—Dr. F. Park Lewis of Buffalo presented this subject to the Association. A committee was appointed to confer and cooperate with a like committee of the American Medical Association and with the committees appointed by other medical societies, to prevent this disease.

Officers.—The following officers were elected for the

ensuing year: *President*, Dr. Richard H. Lewis of Raleigh, N. C.; *First Vice-President*, Dr. Gardner T. Swarts of Providence, R. I.; *Second Vice-President*, Dr. Chas. J. Hodgetts of Toronto, Ontario; *Third Vice-President*, Dr. Manuel Iglesias of Mexico City; *Treasurer*, Dr. Frank W. Wright of New Haven, Conn.; *Secretary*, Dr. Chas. O. Probst of Columbus, Ohio.

Winnipeg, Manitoba, was selected as the place for holding the meeting in 1908.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held April 25, 1907.

DR. HIRAM N. VINEBERG IN THE CHAIR, *pro tem.*

Specimen of Papillary Adenoma of the Ovary.—Dr. LEROY BROUN presented this specimen, which was of special interest because of its unusually large size. The patient from whom it was removed was forty years old, married, having had one child, and one miscarriage. She was a domestic and in good health until May, 1905, when her abdomen began to enlarge. At first this enlargement would diminish by free catharsis, but soon it failed to be reduced in size and a tumor of the right side was noticed. The patient entered the Woman's Hospital after having been in Bellevue for four days treated for supposed pneumonia. When she was first seen by Dr. Broun she was absolutely pulseless and the extremities were cold. After placing her in bed the pulse improved. The respirations were from 40 to 50. A close examination of the lungs showed no evidence of any pneumonic process. There was free fluid in the abdomen. A rapid operation was performed on the day following her admission and a tumor of the right side was removed. There was present albuminous fluid from the ruptured cyst. The patient did well, the pulse becoming stronger. The specimen was from the right ovary and there was also a papillary adenoma of the opposite ovary, not removed on account of the patient's bad condition. Dr. Broun thought that it was generally recognized that these tumors were not malignant in character, and also that they occurred in pairs in fifty per cent. of the cases. There were no adhesions.

Dr. BROOKS H. WELLS said that these tumors, colloid and papillary cysts, were very often malignant.

Dr. GEORGE H. BALLERAY endorsed the opinion of Dr. Wells. In those cases where the tumor had ruptured, there was great danger of the disease attacking the peritoneum; if the tumor was removed before rupture took place, there probably would be no recurrence.

Dr. W. GILL WYLIE said that a great many of such cases seemed to be fatal ones.

Dr. LEROY BROUN said there was a difference between the kind of tumor he presented and one the seat of papillomatous degeneration. These papillary growths were malignant, or readily took on malignancy. If no involvement had taken place by continuity, and if there was no secondary involvement, he believed there was a reasonable chance for recovery.

Specimen of Placenta Prævia.—Dr. GEORGE H. BALLERAY presented a fetus about the fourth month and its placenta; the patient had been the subject of a placenta prævia centralis. He had never seen a case before the end of the sixth month. Multiparity had something to do with placenta prævia. This was Dr. Balleray's fortieth case. When separating the placenta he tore right through into the broad ligament and had to pack the uterus for five days. On the seventh day he removed the stitches. On the eighth day a profuse hemorrhage occurred and the house physician packed. On the tenth day there was another profuse hemorrhage and the woman became almost pulseless. In the operating room she bled, became pulseless, and an intravenous injection was given, which improved the pulse. She was now doing fairly well, all except her anemia. If he had recognized at the beginning what he had to deal with, he said he would have packed the lower segment of the uterus and delivered her later.

Dr. LEONARD S. RAU said he wished to emphasize the point that it was very important *not* to deliver hastily.

Dr. H. N. VINEBERG said that it had always been his rule to empty the uterus at once in these cases. The only fatal cases were those in which the uterus was packed with gauze and kept under observation. He believed the uterus should be emptied as soon as the diagnosis was made.

Two Specimens of Chorioepithelioma Malignum.—Dr. H. N. VINEBERG presented these two specimens, both of which had been removed from women who had borne a number of children and who had later hydatid moles. The first case was that of a woman who had gone ten days over time and began to bleed, and continued to bleed for two months. She had a general anasarca, and a large amount of albumin and casts in the urine, and a tumor that reached to the umbilicus. The question arose as to whether it was a hydatid or a fibroid undergoing sarcomatous degeneration. She was removed to the hospital, operated on, and a hydatid was found. The uterus was emptied and improvement was very rapid. She left the hospital ten days after the operation. At the end of three weeks she again began to bleed profusely and again she entered the hospital and the vagina was packed. When the gauze was removed she again bled so profusely that hastily gauze was packed into the uterus to arrest the hemorrhage. The next day the uterus was removed. The growth presented was found in the right horn of the uterus. The second specimen was removed from a patient forty-seven years old, who had passed her period two weeks and began to bleed. Her general condition was good. He suspected a hydatid mole. She was curetted at the hospital and a large quantity of hydatids were removed. The bleeding did not cease entirely and later it became necessary to remove the uterus. A chorioepithelioma malignum was found.

Why the Ovaries Should Not Be Removed.—Dr. W. GILL WYLIE spoke on this subject. He said this was a subject that he had been interested in for thirty-five years, since he had made a study of women, the ovaries, and the genital organs. For ten or twelve years he had been thoroughly convinced that the ovary had been a much abused organ and a great many things had been attributed to it by doctors. Many ovaries had been removed which should not have been. The gynecologists had been in the late years forced into a peculiar situation. Without question after McDowell, Syms, and others had taken up the removal of ovarian tumors, their success and persistency in advocating this measure led to the right steps in abdominal surgery. Dr. Wylie's early career began in the '70s in Bellevue Hospital, and during that time he could not recall a single case of any kind of abdominal surgery or operation done. No doubt many cases of ovarian tumors were allowed to die. He had never then heard the term salpingitis mentioned. He then went to the Woman's Hospital in 1872-1873, and during his service of eighteen months there he saw not more than thirteen abdominal operations, and they were all selected cases. The death rate was excessive, being often larger than the percentage of recoveries after abdominal operations. In 1882 he entered Bellevue Hospital as visiting physician. Up to that time no abdominal operation for tumor had been successful. Then Dr. Wylie operated upon every case and, of the first 100 cases, he lost ten per cent. At that time the work of Tait and Hegar had attracted attention. Tait was removing tubes and ovaries

for disease, and Hegar was removing ovaries for special growths and fibroid tumors. About that time Battey recommended the removal of ovaries for cases of hemorrhage that was difficult to control; also for severe cases of dysmenorrhea. All this led to great interest in the subject. Dr. Wylie saw a case that had been operated on at Roosevelt Hospital for laceration of the cervix; this case afterwards gave trouble; he found that he could feel a softened and enlarged mass on the side and this proved to be a case of pyosalpinx. This led him to take up the subject. He then began to operate upon these cases. A report to the New York Academy of Medicine of fourteen cases operated upon by him attracted some attention. After a time he found that the removal of the ovaries had other effects than what were expected; in other wards, in a certain class of women, especially in the imperfectly developed, hystcroepilepsy and other nervous phenomena, as well as catarrhal troubles appeared. He soon found that unless he could make a diagnosis of inflammation, which probably would cause an occlusion of the Fallopian tubes, that operation was not justified. Serious nervous conditions were produced and the menopause was precipitated. Also peculiar and marked local changes were produced. It made the young women aged in their genitals, particularly in young women under thirty years. In looking over the catalogues, especially of the general hospitals, he found as many as twenty-five per cent. of the abdominal operations were done on young women for the removal of microcystic ovaries without adhesions. In Washington Remey reported one hundred and twenty-six cases in which only eighteen could be called pyosalpinx and forty had adhesions. After a very careful study of this subject Dr. Wylie had come to the conclusion that the ovaries should not be removed in any woman before forty-five, unless it was necessary to do so to save her life, or for some other good reason. If one took an imperfectly developed woman under thirty years of age and removed both ovaries serious nervous symptoms would develop which would not have developed if portions of the ovary had been left. If one operated upon inflamed or infected tubes, it was best to save a portion of the ovary whenever possible. It had been Dr. Wylie's practice during the past ten or twelve years to treat with more consideration the tubes and ovaries. In removing fibroid uteri he believed that it would be wrong not to leave a portion of, or all of, the ovaries. Our present American life caused young girls to reach puberty with imperfectly developed genital organs, and these were the ones in particular who presented such marked nervous disturbances when the ovaries were removed. In the service at Bellevue Hospital there was a wonderful difference to be noted between the cases and those met in private practice. More than one half of his operations were reoperations, where a former operation had failed to produce the desired results. In many of them the ovaries had been removed to relieve certain symptoms.

Why the Ovaries Should Be Removed.—Dr. Leroy Broun said that the part assigned to him could be divided into three heads, as follows: 1. Ovaries, the seat of gross pathological lesions 2. Ovaries that were cystic in character, hydrops folliculi 3. Ovaries apparently healthy in instances of the removal of the uterus for myomata or other diseases. To the first class belonged ovarian abscesses, cysts, solid tumors, and papillomatous diseases, and conservative surgery in such conditions he believed to mean the entire removal of the ovary. On this point there was no difference of opinion so far as solid tumors and papillomatous disease was concerned. In the effort to preserve even a small portion of an ovary it was the desire of some operators to excise the abscess from its bed and leave some ovarian tissue *in situ*. So also in ovarian cysts was this effort made to leave a fringe of ovarian stroma. It was unquestionably true that such a procedure was anatomically possible, but he could not convince himself that such a procedure in either instance conserved the best interests of the patient. One could not tell by an ocular examination the state of the ovarian stroma left behind after parting it off from the wall of a cyst adenoma, and they could not give the patient positive assurance that a subsequent operation would not be necessary. The same statement held good of an ovarian abscess, but not to the same extent. Here one could excise, or open and drain and obtain a physical relief from the symptoms. At times this relief was permanent. When, however, the patient desired the assurance that no subsequent operation would be necessary, his experience was emphatically against the effort to preserve a portion of the diseased ovary, but to remove the entire ovary. The second class included those ovaries the seat of small blood cysts, or were polycystic, or were cases of "chronic cystic ovaritis." With such conditions it seemed that they could never arrive at a common ground. Dr. Broun's experience in such cases was that the best interests of the patient were conserved in non-operative interference. Many operators had had patients on whom they had punctured cysts, or resected them, and had been rewarded by a complete relief for a time, after which all of the old symptoms returned. He granted that many ovaries might be resected without recurrences; but he also believed that in the majority of these instances the portion of the ovary left would become edematous and as cystic as formerly, with or without a return of the old symptoms. Undoubtedly there existed in a large number of these patients complaining of symptoms referable to the ovaries and in whom they found only a polycystic condition, a marked neurasthenic state; in such cases fresh air, abundant good nourishment, and a proper hygiene would yield better results than puncturing and resection. If it became necessary to operate for any reason, a complete removal of the ovary was preferable, reserving the resections for those patients who might insist that it was preferable to do so, so that a part of the ovary should be left, being willing to assume all responsibility of a possible secondary operation. In supravaginal amputations of the uterus for fibroid tumors or other disease, it was formerly his custom to leave one or both ovaries if they were in an apparently healthy condition, but he had given up this practice and in every instance of the removal of the uterus he removed with it both tubes and ovaries. The ovaries were formerly left in on account of the theory that these organs gave off an internal secretion that would soften the necessary phenomena of the menopause. Dr. Broun had never found any difference in the symptoms of the patients whose ovaries were left, after the uterus had been removed, from those in whom the ovaries were removed with the uterus. In closing Dr. Broun emphatically protested against putting notions into patients' heads about saving parts of ovaries. If they expressed such desires it then was the surgeon's duty to explain to them fully that while such a procedure was possible, yet there were certain possibilities of a failure to a great extent to get relief from the symptoms for which they consulted the physician, and that it might be necessary later on to do a subsequent operation. With these facts laid before them, it was not usual that the patients would elect such a procedure. Their desire was to get well and to be given a reasonable assurance that no further operations would be necessary.

Dr. J. Riddle Goffe wished that this question might be settled and all agree. It was true that during the past years, and up to the present time, gynecologists and general surgeons had not attributed to the ovaries that function, physical, mental, moral, and spiritual that they were entitled to, and it behooved them to correct their latitude and longitude of the thing. He believed that the true

rule for every surgeon to follow when the abdomen was opened and the uterine appendages within reach, especially the ovaries, would be to declare the organs innocent unless they could be proven to be guilty. No ovary should be removed entirely as long as there was any part susceptible of ovulation. In answer to Dr. Broun's query as to how many of these cases returned for secondary operation when the doctor had conserved portion of the ovary, Dr. Goffe said that, in his experience, he had from time to time had cases in which it was necessary to do a secondary operation; but the number of cases in which this secondary operation was required was reduced, compared to the cases in which success attended the conservative work upon these organs. In his cases where the uterus was removed, especially in women under forty years of age, there had been cessation of menstruation for a short time. When he had done a panhysterectomy the nerve storms were something terrific. In the gross lesions of the ovary, dermoid cysts, papillomatous cysts, and sarcomatous tumors all were agreed upon the course of procedure. In hydrops folliculi of the Graafian follicles operators used to remove the ovaries; even Dr. Broun said that these ovaries might be left alone. Dr. Goffe had seen ovaries removed because of cyst of the corpus luteum; yet these cases were never known to develop to such a great size or to give alarming symptoms. A fibroid of the corpus luteum was a small tumor, with yellowish discoloration, irregular in outline, any many men preferred to remove it. Sometimes these might become calcified, but they were perfectly harmless and never led to serious conditions. It was a very lame excuse given when the ovaries were removed because they were sclerotic.

Dr. Brooks H. Wells said he wished to emphasize every word that Dr. Goffe had said. He looked upon the ovary as an important structure. Good surgeons conserved normal tissue; therefore, leave the ovary alone after removal of the fibroid or other conditions of the uterus and tubes, if they are normal. The only cases in which he removed the ovaries were when he dealt with cancer, and in those cases of purulent inflammations of the ovaries and tubes, where the ovaries and tubes were bound together in one mass, the ovary constituting part of the wall of the pus sac.

Dr. Egbert H. Grandin said that all were agreed that when the ovary was not diseased, the woman wanted it, and no good surgeon would take it out. If it was diseased, it was a poor surgeon who would leave it in. With the tubes and ovaries before them, if they appeared healthy, he would be a poor surgeon who would take them out. But there were border line cases in which he defied anyone to state with any degree of positiveness whether the ovary was diseased or not. If an abdomen had been opened because of certain symptoms, and after careful differentiation the symptoms had been referred to one or to both ovaries, as a result of his experience, if he made up his mind that the ovary was diseasd and caused the symptoms, that ovary came out and was not left behind. If an ovary was sufficiently diseased as to require removal, all of it should be removed, and not a part left in. A surgeon aimed to preserve that which was sound, and to remove that which was diseased. No woman went to a doctor complaining of symptoms referable to the ovary, unless the symptoms did come from that ovary. Then, if the abdomen was opened, and the ovary found to be polycystic or otherwise diseased, it should be removed. In purulent disease, especially gonorrheal, he said they should not stop short of taking away both ovaries. A diseased ovary had no favorable influence on a woman; a woman with a diseased ovary was not as healthy as when without a diseased ovary.

Dr. George H. Balleray said the point was whether or not the patient was suffering from pathological conditions referable to the ovaries. What was the real cause of the pain? Was it some pathological condition of the ovary? If so, the ovary should be removed.

Dr. William S. Stone said that if we took ten women of the same age, on whom the same operation had been performed, for instance, a supravaginal hysterectomy with the removal of ovaries and tubes, it would be a fact that the changes in the external genitals would vary a great deal. Did the character of the operation determine these changes? It did not. These results, especially in women under thirty years of age, varied greatly. In cases of gonorrheal pus tubes, a long-continued discharge from the uterus might have something to do with determining the subsequent condition of the external genitals. Older women who had suffered for years from a gonorrheal discharge from the uterus were apt to have severe atrophic changes of the vagina and external genitals.

Dr. H. N. Vineberg cited a case to illustrate his own practice. A woman had been brought to the hospital who had had an operation performed by another surgeon two years previous; he had removed the tube and ovary upon the left side. She had symptoms from a hernia, and much pain on the right side. He decided to open the abdomen and cure the hernia. He found at operation that a cyst occupied one-half the remaining ovary. She was but twenty-two years old, so he removed the cyst, and stitched together the remaining portion of the ovary. Recently a physician asked him about a woman whom he had delivered. The woman was this patient. She had been perfectly well. In this case both tubes were removed and only a small portion of one ovary was left behind. Dr. Vineberg felt that in young women, even though they might have to open the abdomen again, it was better to leave some ovarian tissue behind. When there was an inflammatory condition of both tubes and ovaries, and a diseased uterus, the question then arose whether it would be best for the patient to remove everything. In those cases where a portion of the ovary was left behind it was not so much the ovary that caused trouble, but the uterus.

Stated Meeting, Held May 23, 1907.

Dr. Howard C. Taylor in the Chair.

Paralysis of Both Upper Extremities, Following Pelvic Elevation, or Trendelenburg Posture.—Dr. Herman J. Boldt presented a woman who was operated upon on March 5, 1907, for the removal of an intraligamentous myoma. The tumor was pedunculated and originated from the left side of the uterus. Technically the operation was difficult, so that the patient was in the position of pelvic elevation for about three-quarters of an hour. The paralysis was present immediately, and was recognized as soon as the woman had recovered from the anesthetic. While one neurologist of repute considered it to be from another cause than posture, there was, in his opinion, no ground for such assumption. So far the woman was still a complete invalid. Dr. Boldt said he did not know of another instance on record of such total paralysis. In the cases so far observed recovery soon occurred.

A Series of Specimens of Extrauterine Pregnancy.—Dr. Louis J. Ladinski said that the specimens he presented were removed from patients who had entered his service at the Beth Israel Hospital during the past few months, and consisted of every form and variety of extrauterine pregnancy, thus affording a most interesting and concise exhibition of the entire subject from a clinical standpoint. Before demonstrating these specimens, he gave the cardinal signs and symptoms in the order of their importance, which, in his opinion, were pathognomonic of the condition. *Signs.* (1) First in importance was a negative sign, the exclusion of intrauterine pregnancy. This was readily accomplished by employing the sign of early pregnancy that he advocated in a paper recently published. (See Medical Record, Vol.

71, No. 15, April 13, 1907, page 597.) (2) Enlarged uterus. Consistency of uterus similar to normal uteri. (3) Bleeding from the uterus. This did not, as a rule, occur before the sixth or seventh week of pregnancy, but after that period it was present in nearly all cases. Bleeding from the uterus might, however, cease sooner or later after the pregnancy was interrupted, in consequence of a tubal abortion, or after a perforation or rupture of the tube. (4) Characteristic mass on one side. A tube distended, either in the isthmal, ampular, or infundibular portion by a gravid sac presented a fusiform, elastic, tender mass, which, from its shape, location, mobility, sensitiveness, and peculiar feel, could readily be differentiated from a hydrosalpinx, pyosalpinx, ovarian, and parovarian cysts, and pelvic tumors. *Symptoms* (1) Amenorrhea, which was invariably present, though a history to that effect might not always be obtained. (2) Pain, paroxysmal in character, was always present and was referred to the affected side. (3) Negative symptom, which was of value only before rupture, was an absence of elevation of temperature. In the presence of all these signs and symptoms, a positive diagnosis could invariably be made. In the absence of some of the above signs and symptoms, a probable diagnosis might be made, and it was even safe to make a positive one if there were not present additional symptoms referable to other lesions. The signs and symptoms given referred to the stage prior to rupture. At the time of rupture, or immediately following it, there were the additional well-known signs and symptoms of shock, sudden pain, and internal hemorrhage. The condition to be diagnosed subsequent to the rupture that destroyed the products of conception had to do with a pelvic or abdominal hematocele or abscess. With the exception of two or three cases in his series, which numbered now about 100, the abdominal route was the one of choice. The operation was performed as soon as a diagnosis was made and consent given. Shock and collapse and extreme anemia were not considered contraindications to operation. In several cases the collapse was so marked that an anesthetic was not required. Intravenous infusion was resorted to to sustain the patient before, during, and after the operation, according to the requirements of the case. Free blood and clots from the peritoneal cavity were removed with hand or wiped away with moist pads or strips of gauze. No irrigation of the peritoneal cavity, or drainage in any case, was employed. He had lost but a single case, and that patient died of a tertiary hemorrhage on the fourth day after the operation, in which there was, in all probability, a rupture of a varicose vessel in an hemophiliac, and was not tubal pregnancy at all.

Almost Fatal Hemorrhage from Ectopic Gestation Without Rupture of the Tube Wall; Operation and Recovery.—Dr. Philander A. Harris of Paterson, N. J., presented this specimen, a well-formed fetus about 1⅜ inches in length, and the amniotic cavity from which it had escaped through knife dissection occupied presumably two-fifths of the dilated tube. Surrounding the amniotic cavity, and filling the interspace between it and the tube wall, could be seen an almost uniform layer of organized clots about one third of an inch in diameter. The patient was 27 years of age, married, first menstruated at the age of 12, and regularly every twenty eight days until the present illness. She always had terribly severe pains the first day of menstruation. The menstrual term lasted five to six days, and she soiled eighteen to twenty napkins. No pregnancy until the present tubal pregnancy. Her last menstruation occurred February 12, 1907. After that she saw no blood until the 16th or 17th of March. Then she had a little pain across the hypogastrium and the appearance of blood in the vagina. A little blood appeared almost daily from March 17 until April 1 or 2. On April 21 she had severe pains in the hypogastrium, which were more severe on one side of the pelvis than on the other. She also vomited. This very severe pain lasted about one-half an hour. April 22 she felt somewhat tender across the lower abdomen. April 23 she had a very severe colic in the hypogastrium; this was attended with pain in the right shoulder. She vomited three or four times. The colic lasted half an hour. Again, on April 25, she experienced severe pain in the epigastric region; she vomited, and she said she felt as though she was dying. Her physician, Dr. Tuers, was sent for and found her almost exsanguinated. He at once diagnosed the condition as one of tubal pregnancy. Dr. Harris saw her one hour later. There was no pulse at the wrist, and the patient said she was thirsty. She had extreme palor, but did not exhibit the restlessness which was so often seen in the tragic stage of tubal pregnancy. She was taken to the hospital, placed on the operating table, a few whiffs of ether were given, and an intravenous injection given. The abdomen was opened and a pint or two of dark fluid blood was removed, and a lot of large dark clots were taken from the cul-de-sac of Douglas and a distended right tube, measuring two inches in diameter and apparently still enveloping the fetal products, was tied off and removed. She was sent to her room with a pulse of 130, respiration of 40. The blood which was found in the peritoneum in this case escaped from the ostium abdominale. There were no evidences of a destruction, or even a perforation, of the walls of the distended tube. The patient made a rapid and complete recovery.

A Case of Tight Knot of the Cord, with Consequent Antepartum Death of the Fetus.—Dr. Robert A. Frank reported this case. The patient was 31 years old; had had one living child nine years before, the labor lasting thirty-six hours and requiring low forceps. The present pregnancy was normal. There was a slight excess of liquid amnii, but no true hydramnios. The fetal movements were first felt during the sixth month. Within one-half hour of the onset of labor the membranes ruptured, the liquid being dark in color but without odor. Frequent but inefficient pains occurred for thirty-two hours, by which time the cervix was nearly fully dilated. Delivery of a large child was accomplished by high medium forceps. The last fetal movements were felt one day before the onset of labor, and no fetal heart-sounds were heard throughout the labor. The child was dead, but fully developed, and showed signs of beginning maceration. The placenta was normal. The cord was 90 cm. in length; 30 cm. from the placenta was a simple, very tightly-drawn knot, which caused deep indentation of Wharton's jelly. Above the knot the vessels were dilated; below the knot they were empty, contracted, and almost invisible. Only nineteen authentic cases, in which fetal death was due to the same cause, were found in a search of the literature. As loose knots occurred in 0.5 to 1 per cent. of all births, it was surprising that the tightening of the knot was so uncommon, especially as it had been experimentally determined that a traction of 25 to 90 gm. exerted upon a knotted cord sufficed to cut off the fetal circulation.

Chorioepithelioma. Remarks on Microscopical Diagnosis, Prognosis, and Relation to Cysts of the Ovary.—Dr. James Ewing read this paper. He said that since Marshand first described the origin and nature of chorioepithelioma, in 1895, an extensive literature had accumulated, and the main points at issue concerned the variations in structure, the possibilities of basing a prognosis on the microscopical appearances, the existence of a benign type, and the relation of cysts of the corpora luteum to chorioepithelioma. There were considerable variations in the structure of this tumor. There were at least two rather characteristic histological pictures encountered: (1) The usual structure presented an extensive growth of huge branching and papillary masses of syncytium, associated with thick cords and islands of the smaller polygonal Langhans cells and covering placental villi, which were themselves often thickened by a new growth of mucoid connective tissue. The villi were sometimes missing, but since

finding them in a tumor which had extensively infiltrated a large portion of the uterine wall, he had not regarded their presence as a sign of malignancy. The masses of syncytium were very prone to invade the perivascular lymphatics, thus early penetrating the deeper portions of the endometrium, while their remarkable capacity to erode and enter the uterine veins was the chief basis of the repeated hemorrhages and of the early and extensive metastases. (2) The tumor cells were of more uniform size, typical syncytium, Langhans cells, and villi, could not be distinguished; but most of the cells appeared to be derivatives of the syncytium, being of large or giant dimensions. An origin from the syncytium or Langhans cells might sometimes be shown by the occurrence in some tumors of intermediate forms between syncytium and these large tumor cells. Accepting the current dictum that the large cells, which extensively invaded and even traversed the uterus in normal gestation, were derivatives of the syncytium, this tumor was a chorioepithelioma. Probably there were transitional tumors between these two types of chorionic tumors. With regard to benign chorioepithelioma, Dr. Ewing said that it was early observed that while the majority of chorioepitheliomata pursued a malignant course, yet others of apparently identical histological structure progressed with every evidence of a malignant character, but after a time, when the growth was interrupted, perhaps by partial removal, instead of going on to its usual fatal termination, the process completely subsided and the patient recovered. The result was all the more remarkable in view of the long interval, two years sometimes elapsing between the first appearance of the growth and its attempt at removal and the final outbreak of interval metastases and fatal cachexia. In the present state of knowledge of chorioepithelioma, the following conclusions seemed to be valid: (1) Two processes, histologically distinct, were being described as chorioepithelioma, as above described. These tumors of the first class were all potentially malignant; but at least one had been cured by curettage, and others had subsided after incomplete removal, even after internal metastases had occurred. They occurred usually after early abortion or followed hydatid moles, were usually circumscribed, tended to perforate the uterus early, and, unless associated with hydatid moles, might not cause much enlargement of the uterus. These tumors of the second class usually developed slowly, greatly enlarged the uterus, and possessed only moderate malignancy. It might be difficult to distinguish them from a harmless cell invasion. These tumors might be properly called atypical or benign chorioepithelioma. (2) When typical proliferating syncytium and masses of Langhans cells appeared in the curettings, the process was always potentially malignant. Curettage in the early stages and partial removal after perforation of the uterus and metastases had arrested the process, but this result was dependent upon local circumstances or on the general resistence of the patient, and should not be accepted. When curettage showed only syncytial wandering cells, curettage was a safe initial procedure, unless the local condition suggested extensive involvement of the uterine wall. (3) The presence of true decidual tissue in curettings was no guarantee that a malignant chorioepithelioma did not coexist. After reporting a case of primary carcinoma of both Fallopian tubes, Dr. Ewing said that Orthmann had collected 84 cases of primary tubal carcinoma, some of which were bilateral. Of these, 44 were preceded by chronic inflammation of the tube, pyosalpinx in 26, tuboovarian cysts in 10, atresia of the abdominal ostium in 7, extensive chronic inflammation in 1. He pointed out that tubal cancer was rarely associated with uterine, but frequently with ovarian cancer. In 17 cases of widespread uterine cancer, Orthmann found no tubal involvement; in 18 of ovarian carcinoma or sarcoma, the tubal involvement occurred in ten. With regard to sarcomatous degeneration of fibromuomata, in 1,880 cases of fibroids 48 showed sarcomatous changes. Cullen had recently reported 17 instances of sarcomatous transformation or degeneration of uterine fibroids. In regard to most of these cases, the question might be raised whether the presence of certain very cellular foci in an ordinary fibroid was sufficient evidence to warrant the conclusion that the tumor was sarcomatous or had changed its character. Such a conclusion would seem to demand the demonstration that an ordinary fibroid had existed for some time, and then, coincident with rapid increase in size, had completely changed its gross and microscopical appearance.

Seventh Annual Conference of the Sanitary Officers of the State of New York.

This Conference was held in Buffalo on October 16-18, the first meeting being called to order on Wednesday afternoon, October 16, by Dr. Ernest Wende, Health Officer of Buffalo. Mayor Adam and Mr. Gratwick, Chairman of the Chamber of Commerce, delivered addresses of welcome, after which State Health Commissioner Eugene H. Porter delivered the annual address. He first outlined the work accomplished by the department during the past year, especially the investigation of summer resorts and of the sanitary condition of various cities in the State. The number of summer resorts was so numerous that, with the money at the command of the department, it was impossible to inspect them all in a single season, but it was hoped that the work would be so far completed next year that many cases of "summer-resort typhoid" would be prevented. An investigation of the conditions favoring the spread of typhoid fever in a number of the towns and municipalities of the State had also been made and the results were being tabulated. When these reports were finally passed upon the department believed that it would be able to give to each of these municipalities substantial aid in correcting the existing dangers to health and life. But the department did not undertake to do the required work. The town must work out its own sanitary salvation. In order to gather information regarding the pollution of the streams and lakes of the State, a sanitary survey had been made and sanitary maps had been proposed of many of the water sheds, those of the Oswego, Upper Hudson, Lower Hudson, Susquehanna, Genesee, and Niagara being now practically completed. All of the public water supplies and sewage disposal plants in the State had been looked into and samples had been tested. Reference was made to the examinations of the eyes and ears of school children about to be conducted by the teachers in incorporated villages of the State. In the State Hygienic Laboratory examinations of meats, beers, wines, and whiskies had also been conducted, which showed an improvement in the character of these food supplies. Attention was called to the tuberculosis exhibition, which it was announced would be loaned to various municipalities through the State at the conclusion of the conference. Special circulars on sanitary matters for popular distribution were under preparation by the department. Although the appropriations for the department had been increased by almost $42,000, in comparison with other States the New York department was receiving a very inadequate money supply. Reference was made to the Cancer Laboratory in Buffalo, and the commission took occasion to remark that the health officers should as far as possible allay the disquietude of the public on the subject of the contagiousness of cancer. The department was not at present able to endorse the recommendation of the Medical Society of the State of New York, that all candidates for the position of health officer should be possessed of a special diploma in public health.

At the second session of the Conference there was a "Symposium on Tuberculosis." Prof. V. A. Moore of the New York State Veterinary College at Ithaca read a paper on the dissemination and control of tuberculosis as illustrated in the bovine species. Attention was drawn to the large number of tuberculous cattle scattered throughout New York State, and the need of adequate supervision and

control over these infected animals was pointed out. Dr. JOHN H. PRYOR, trustee of the New York State Hospital for Incipient Pulmonary Tuberculosis, dealt with the early diagnosis and treatment of tuberculosis. Dr. EDWARD DEVINE of New York City, secretary of the Charity Organization Society, dealt with the social aspects of tuberculosis.

At the third session Dr. ADNA F. WEBER, Chief Statistician of the State Department of Labor, read a paper on "Labor Legislation in Its Relation to Public Health," in which he drew attention to the various sections of the labor laws of the State which dealt with the health of employees, making special reference to the child-labor law.

THEODORE HORTON, the Chief Sanitary Engineer of the State Department of Health, discussed "Sewage Disposal for Institutions and Small Communities."

At the fourth session, Dr. JOHN T. WHEELER, Director of the Division of Communicable Diseases, read a paper on "Practical Points on Quarantine," in which he emphasized the need for prompt diagnosis of smallpox and a thorough vaccination of the community. He also urged the health officers to use antitoxin freely for abortive and preventive purposes in diphtheria. Then followed a "Symposium on Medical School Inspection." Dr. H. E. SCHMID, President of the Board of Health of White Plains, advocated placing in the hands of teachers circulars in which the early symptoms of the common communicable diseases were outlined, so that they could aid in the early recognition of cases occurring among their pupils. Dr. HARLAN P. COLE of New York City, Consulting Orthopedist of the State Department of Health, discussed physical defects in school children, referring to the need of examining children's teeth, of encouraging a development of the full lung capacity, and particularly of looking out for the minor departures from the normal so often seen in school children and which later, following an attack of acute disease when the power of accommodation has been lost, might develop into marked deformities. Dr. HERBERT D. SCHENCK of Brooklyn, Consulting Ophthalmologist of the State Department of Health, dealt with the detection of defects of the eye, ear, nose, and throat, making special reference to and giving the details of the examination about to be conducted in the schools throughout the State.

The sixth session was omitted to give the members an opportunity to visit the Buffalo stockyards and the packing houses, under the direction of Dr. Benjamin P. Wende, Inspector in Charge of the Federal and Municipal Meat Inspection Bureaus.

The seventh and closing session of the Conference was devoted to a "Symposium on Pure Milk," to suggest what health departments can do to secure the same. Dr. THOMAS DARLINGTON, the Health Commissioner of New York City, showed what could be accomplished by the inspection of dairies and farms. He believed that this was the only practicable method of dealing with the problem for large cities whose milk supply was drawn from a very widely scattered territory. Dr. ERNEST WENDE of Buffalo followed with an address on the permit and license system, and Dr. HENRY R. HOPKINS still further developed the idea of control of the production and sale of milk by the "telltale" milk register, which enabled a health department to trace the source of milk suspected as a means of conveying contagion. Dr. GEORGE W. GOLER, Health Commissioner of Rochester, spoke of what he had done and what had been done by other health authorities in improving milk supplies by educational measures. The address was illustrated by stereopticon views. The last paper of the evening dealt with the use of the score card system and was read by ELLIS W. SANTEE, M.D., Dairy Expert of the United States Department of Agriculture. This, too, was illustrated by stereopticon views. The Conference closed with resolutions of thanks to all those who had contributed to the success of the Conference and to Commissioner Porter for the work that he was carrying on for the protection of the health of the people of New York State.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 26, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	350	137
Diphtheria	313	18
Measles	142	9
Scarlet Fever	208	8
Smallpox	..	..
Varicella	40	..
Typhoid Fever	106	23
Whooping Cough	6	2
Cerebrospinal Meningitis	6	8
Malarial Fever	..	..
Totals	1171	205

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service during the week ended October 25, 1907:

		CASES.	DEATHS.

KUHN'S LUNG SUCTION MASK FOR THE HYPEREMIC TREATMENT (BIER) OF PULMONARY TUBERCULOSIS.

By WILLY MEYER, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN HOSPITAL; CONSULTING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL AND NEW YORK INFIRMARY.

THAT artificial hyperemia alone can cure a tuberculous process, belonging to the domain of surgery, is an established fact. This important principle in our therapeutic resources was discovered by Bier fifteen years ago. It has been shown that, if the treatment be properly and faithfully carried out—in most cases requiring many months of patient application—the functional results in the cures of tuberculous joint disease, obtained by this method, are often superior to those resulting from the use of the knife, chisel, and saw.

One of the many tasks that still await solution in connection with this method is the proper practical adaptation of the principle, involved, to the various types of tuberculous disease belonging to the domain of internal medicine and the specialties, principally to pulmonary tuberculosis.

It is self-evident that tuberculosis of the lungs must yield to hyperemic treatment just the same as do tuberculous affections of the joints, tendon sheaths, testicles, etc.

Nature herself has demonstrated this again and again.

I would repeat here that the idea of making use of an increased volume of blood for the purpose of combating surgical tuberculosis was conceived by Bier as a result of his studies of the observations, made by other authors, almost a century ago, namely, that tuberculous pulmonary foci are found with great frequency in individuals with heart lesions causing an *anemic* condition of the lungs, while in the presence of a *hyperemic* state of the latter they are rarely found. Farre and Travers (1815), Louis (1826), and Frerichs (1853) have shown by numerous post-mortem examinations, that patients afflicted with stenosis of the pulmonary artery are very liable to be stricken with phthisis, whereas Rokitansky in 1838 proved on basis of his large dissection material at the Vienna hospitals, that tuberculosis of the lungs is extremely rarely found in combination with venous pulmonary hyperemia due to valvular disease of the heart or deviations of the spinal column, in fact, that tuberculous foci in the lungs heal and show the characteristic cicatrization in the presence of such heart lesions. According to his statistics there were among 143 cadavers with a hypertrophic heart fifteen that showed traces of the previous existence of a tuberculous process in the lungs. The rest showed no signs whatever of any such disease.

Many other interesting proofs of the fact *"that the amount of blood within the lungs determines the degree of liability of the patient to pulmonary tuberculosis,"* are cited by Kuhn. It would lead me too far to enumerate them here.

Greatly impressed with the importance of these facts, it is but natural that Bier should have suggested trying his "Stauungs-hyperaemie"* also upon phthisical patients.

In 1903 he proposed the very simple manipulation of making these patients inspire through the nostrils under slight compression of the nose, allowing them unobstructed exhalation through the mouth. Lately he also used glass suction apparatus of various sizes and shapes, principally over the apices of the lungs.

Two years later, Leo of Bonn revived the proposition made by Jacoby, who tried to accomplish the same end by placing the patient in a pronounced Trendelenburg posture. Of course, this procedure is rather disagreeable for the patients, and less effective, since in this way the blood can only *gravitate* to the lungs. However, the method, if applied in moderate degree, should not be lost sight of as an adjuvant.

The third to advance a useful and generally applicable method, was Ernst Kuhn of Berlin, military surgeon and assistant to v. Leyden, at the Charité Clinic. He constructed the so-called "lung suction mask," which I beg to show you to-night.

The subject of Bier's treatment having been of greatest interest to me for many years, I hope you will forgive the surgeon for trespassing upon your domain. Besides, we so often find tuberculous pulmonary affections in connection with surgical tuberculosis, that, naturally, the surgeon too is directly interested in this burning question.

The construction of Kuhn's mask is based on Bier's original idea of having the patient inhale in a slightly obstructed manner, so as to produce negative pressure in the thoracic cavity. We know that the respiratory distention and contraction of the thorax is automatic, a physiological act. Now, if we prevent the easy filling with air of the elastic lung tissue, as is the case under ordinary circumstances, when the thorax expands during the act of inspiration, the air within the lungs is rarefied and the blood aspirated. In other words, we produce an artificial hyperemia of the lungs by suction.

It was evident, however, that it would be an advantage to be able to increase or decrease this hyperemia by degrees, and it was with this point in view that Kuhn proceeded to construct his lung suction mask. Made of thin celluloid, the mask has the shape of the mouth piece

*A short word, covering the principle of the procedure, is not to be found in the English language. "Obstructive Hyperemia" might be suggested, but the word represents the cause only, not the effect. "Stasis Hyperemia" would be an absolutely false interpretation of the process. What pathologists call a stasis is exactly what must be prevented in applying artificial hyperemia. "Artificial" or "Passive Hyperemia" also expresses but poorly the mechanical cause and physiological effect of the procedure.

we use to cover the patient's face with when administering one of the volatile drugs for general anesthesia. (Fig. 1.) The edges here, too, are protected by rubber tubing which can be filled with air. The mask is divided transversely by means of a celluloid wall, which rests with its border on the upper lip. This border also is provided with an inflatable pad. In this way we have two separate cavities, one for the nose and one for the mouth, there being no communication except by a slide covering a narrow slit in the transverse dividing wall. This slit is opened only if nasal respiration is temporarily or permanently interfered with. The mask is placed over nose and mouth of the patient and held in place by two elastic straps passing below the ears and fastened in the back by means of a buckle. (Fig. 2.) Another slide, attached to the outer side of the nasal section of the mask, controls the degree of obstruction desired. (Fig. 1A.) This is the principal part of the device, inasmuch as by it we regulate at will and by degrees the amount of obstruction to the passage of air into the alveoli of the lungs. It has a scale of 6°, and covers a slit somewhat less than 1-16 of an inch (1 millimeter) wide and somewhat longer than the one in the partition membrane between mouth and nose cavity. Two caps, that can be screwed off, each embracing a small celluloid plate, form the valve for expiration, same as we find this in the ordinary narcosis inhalers. (Figs. 1B and C.)

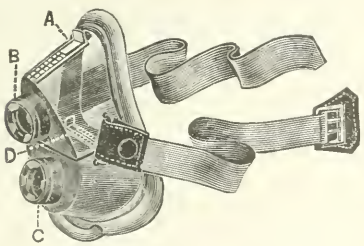

Fig. 1.—The Kuhn Suction Mask

If the regulating slide be entirely open, the patient can inhale quite some air, but naturally never as much as without the mask.

Inspiration is done through the nose and expiration either through the mouth alone or through both mouth and nose.

Of course, if desired, the valve over the mouth section of the mask could be entirely removed. But this should be done in the case of intelligent patients only, as then special attention has to be paid to the act of respiration. During sleep this valve, too, should always be in place.

The mask is worn in the beginning 2-3 times a day for 15 minutes; later, the time is increased to 1 hour 2-3 times per day. The primary unpleasant effects from wearing the mask, consisting in headache and dizziness will not last, but disappear quickly as the applications are continued.

While using the mask the patient would best rest on an easy chair on the piazza or near an open window.

Disinfection is done (with the rubber straps unbuckled) in a *cold*, three per cent. solution of lysol or carbolic acid. Afterwards the mask is rinsed in cold water in order to get rid of the odor of these disinfectants. It is advisable to remove the two caps on top of the mask often and clean and dry the small celluloid plates. They are apt to become sticky, but proper care must be taken to always have them work easily. It must be borne in mind that celluloid is a very combustible material.

It is interesting to know that the idea of improving the condition of phthisical patients by influencing respiration has been worked out by a number of men many years ago.

It is thanks to the courtesy of Dr. E. R. Baldwin of Saranac Lake that I am able to tell you something about this to-night. Three weeks ago I had to visit one of my patients residing at Saranac Lake, and took up with me Kuhn's mask, which I then just had imported. I showed it to Drs. Baldwin and Allen up there, and the former told me that a colleague in New York City, Dr. Chas. E. Quimby, worked along these lines for years and that also a number of advertising men outside of the profession had evidently tried to accomplish the same purpose by means of various similar, though much more complicated devices than the one I could show to-night.

I beg to here read the letter I received from Dr. Baldwin, under date of October 4:

"My dear Dr. Meyer:

"With reference to the various therapeutic measures which have been employed in the past and which, in some degree, have embodied Bier's hyperemic principle as applied to pulmonary tuberculosis, I would mention the following:

"An empirical device introduced by the Rev. Dr. Buckley, the well-known leader of the Methodist-Episcopal church, who himself was said to have had tuberculosis and been much benefited by the use of a breathing tube, containing a ball valve which, I think, was arranged to impede expiration. There has been on the market also a tube known as the Howe breathing tube, which was a somewhat similar contrivance. I have already given you a picture of a device introduced by Dr. Dennison of Denver, the mechanism of which I am not familiar with.

"These empirical devices do not, however, compare in importance, in my opinion, with the use of the pneumatic cabinet which, although long since discarded by most phthisio-therapists, has been persistently used by a few, notably Dr. C. E. Quimby of New York. While the rationale has been somewhat different, I believe Dr. Quimby's theories and practice of the cabinet method have included Bier's principles in effect.

"These are the only things bearing on the history of the subject that have casually occurred to me, but I trust they will serve your purposes.

"Yours very sincerely,

(Signed) "Edward R. Baldwin."

All these men have been more or less on the right track.

To-day, thanks to Bier, we know the *true scientific principle* of their success, and this principle is: Intermittent artificial hyperemia, so-called "Stauungs-Hyperaemic." To-day we are in a position to let *every* patient suffering from phthisis benefit from this "physical method of treating pulmonary tuberculosis" in a simple and, at the same time, agreeable manner.

I have no doubt that this mask will soon be found on the market in a variety of designs, although I think the closer they adhere to Kuhn's model the better.

I myself intended to bring out—with the help of the Kny-Scheerer Co.—a mask made of aluminum. This would have had the advantage of being easily disinfected by boiling—which, of course, cannot be done with Kuhn's celluloid mask; besides, it would be non-combustible and rarely in need of repair, and

if so, this could have been attended to here; furthermore, the mask would have been considerably cheaper than the Kuhn mask, the present market price of which is $8. Unfortunately a U. S. patent on Kuhn's mask forbids this. However, negotiations have been entered into for the purpose of overcoming the obstacles if possible.

Those who cannot or do not wish to spend any money for such a mask, that can be conveniently regulated, may, of course, improvise methods to obstruct inspiration. For instance, they may obtain obstruction to inspiration by placing eye-glasses or some kind of a clamp upon the nostrils, controlling the degree of obstruction by placing them higher or lower. Furthermore, small, perforated corks may be placed within the nostrils, the degree of obstruction to be controlled by the size of the perforations. Empty spools with holes of various calibers may be put into the mouth and held by the teeth, the lips closing air-tight around the spool, will produce obstructed mouth-inspiration, etc. This latter device, will, of course, be found rather annoying to the patient on account of the effect it will have in drying out the mouth and the respiratory passages. All these devices or methods are rather crude, and do not permit of any such exact regulation of the degree of obstruction as the apparatus I have shown you this evening.

Personally I have used the mask on three patients, one of them having pulmorary disease connected with tuberculous bone lesions. Another, a young man of 23 years, who had hemoptysis a year ago and spent the winter in Texas, is using it since the early part of August. He is here before you to-night. He spent the summer months at the hotel, where I stopped, he acting as head of the telegraph office. I got interested in his case and gave him one of the few masks imported for me. He applies it three times one hour daily and feels, subjectively, a decided improvement in his general condition and there is much less coughing. He expects to go to Colorado soon and will, of course, continue the regular use of the mask for several years to come.

The advantages of the mask, as pointed out by Kuhn, are principally two-fold:

1. The healing of the tuberculous foci in the lungs by "Stauungs-Hyperaemie" (Bier);

2. The increase of red and white blood corpuscles as well as hemoglobin in the blood.

It should be specially emphasized here, that the application of the mask is not known to have done harm in a single instance.

For further details I would refer those interested in the question to Kuhn's original articles in the *Deutsche medizinische Wochenschrift*, 1906, No. 37 —to his later article and that of Stolzenburg, both in *Münchener medizinische Wochenschrift*, April 16, 1907, as also to Kuhn's latest paper in the *Münchener medizinische Wochenschrift*, 1907, No. 35.

Here I will but mention:

1. That the beneficial influence of the mask will naturally be best shown in cases of *incipient* pulmonary tuberculosis, or better still, when used as a prophylactic.

2. That also advanced cases are greatly benefited by it, *as long as chronic toxemia and pronounced weakness of the heart do not render impossible any kind of improvement.*

3. That the risk of hemorrhage from the lungs does not forbid its use; on the contrary, there seems to be a diminished liability of a return, as the granulations in the lung tissue apparently get stronger under the application of the mask, same as we observe this in granulations on the surface of the body, while under hyperemic treatment.

4. That post-mortem observation of the lungs of a patient who died of chronic intestinal tuberculosis and in whom the mask had been used for several months, has shown the foci isolated and surrounded by a mass of new-formed connective tissue, the latter being in the stage of cicatrization. Further observations of pathologists will be received with great interest.

5. That, on account of the larger quantity of blood being aspirated into the lungs, more oxygen enters the circulation; furthermore, that in consequence of the resistance offered to inspiration, the entire system of respiratory muscles is strengthened, on the basis of the idea underlying the well-known "Swedish movements" method.

6. That by thus improving the constituency of the blood, the use of the mask not only incidentally improves the usual anemia of phthisical patients, but promises to become one of the most powerful physical aids, so far known to us, in our fight against ordinary anemia.

7. That, according to the degree of obstruction to inspiration arranged for, the mask produces the effect of various high altitudes on the general system, that is to say, it rapidly increases the number of red and white blood corpuscles, of the latter especially the polynuclear neutrophiles, and the percentage of

FIG. 2.—The suction mask in position.

hemoglobin. This is produced by the irritating effect of the condition of reduced tension of oxygen in the blood on the blood-producing tissues of the body, principally on the bone-marrow.

Inasmuch as the increase of the blood elements begins very early, one hour after applying the mask, it will be interesting to watch whether this obstructed inspiration might not be used to advantage in surgical patients, especially after abdominal operations, to produce artificial leucocytosis.

8. That the mask incidentally has proved of great benefit in relieving the pulmonary circulation in cases of advanced valvular disease of the heart, as also in cases of obstinate asthma.

This physical treatment of pulmonary tuberculosis will, of course, not do away with the well-tried and time-honored treatment by means of tuberculin,* pure air, rest, forced nutrition, proper drugs, etc.

It is but another, though *most important link* in the chain of our therapeutic resources in the fight against and probable ultimate conquest of this scourge of mankind.

It increases the natural protecting forces of the organism, by means of strengthening the normal functions of the body.

*The effect of tuberculin injection will probably be increased by artificial Stauungs-hyperaemie." (Leo.)

It will prove to be of especial value in dispensary practice and in the treatment of such phthisical patients as are not endowed with the riches of this world and cannot afford to leave their homes and their families.

I, therefore, believe that Kuhn's mask for the treatment of phthisical patients should be promptly introduced into sanatoria as well as in private practice, thus allowing also *patients afflicted with pulmonary tuberculosis* to benefit from Bier's wonderful discovery.

700 Madison Avenue

RADIUM FOR THE TREATMENT OF CANCER AND LUPUS.*

By WILLIAM J. MORTON, M.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, AND ELECTROTHERAPEUTICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In the absence of a positive cure for cancer, surgical or medical, every real aid in the treatment of this disease is worthy of present study, not alone for the quota of good it itself may accomplish, but also as affording a clue to further advances.

This paper is simply a contribution to radium therapy, fortified by citation of a few selected cases. The writer begs to disclaim any intention of putting forward radium (or anything else) as a "cancer cure." This remark is made because at the present moment there seem to exist in some quarters a remarkable psychological state of mind which apparently blinds its possesors to the obvious fact that searchers for truth may impartially report facts and efforts to treat cancer, or even report cures of *some* cases of cancer without in the least wishing to be understood that the same method will cure *all* cases. Certainly the Roentgen ray, radium, and in my opinion trypsin and amylopsin, all and each when properly applied exert a deterrent influence upon the growth of the cancer cell, and until the moment of the advent of a cure for cancer as positive as is the cure of syphilis by mercury, I believe that the practitioner may avail himself usefully of the above, as well as of other agencies.

The Roentgen ray, now beyond question, cures many cases of superficial cancer. But in actual practice it has seemed to me that radium is superior to it in similar cases, granting that we employ the pure radium salt, and again for an actual attack upon a cancerous tumor the Roentgen ray can never be as successfully applied as can radium by the art of embedding it in a suitable receptacle within the cancerous mass. Other reasons for advocating the therapeutic value of radium may be briefly given as follows:

1. Accuracy of dosage. One may use a standardized pure radium bromide of a carefully measured radioactivity. This radioactivity is invariable and the measure of treatment, therefore, may be couched in terms of time units, as, for instance, a total of so many minutes or hours, either at one sitting or consecutively. The difficulty, if not the impossibility, of accurate measurement of Roentgen ray dosage is well known.

2. As regards the gamma rays of radium, their penetrating power by reason of their greater velocity, has been shown to be much greater than that of the Roentgen ray. We may, therefore, expect and do actually obtain a deeper and wider action.

3. In the use of radium, if enclosed in aluminum or mica receptacles, we utilize the beta or cathode ray. This we cannot do in Roentgenization except accidentally and as secondary radiations due to the impact of the *x*-rays. This fact gives the practitioner, for the first time in medicine, the opportunity of directly using the cathode ray, viz., the negative particle; and this differentiates radiation by radium very strongly from radiation by the Roentgen ray. This fact alone would lead us *a priori* to expect different, if not also greater therapeutic effects due to the well-known, powerful, ionizing, chemical, and photographic effects of these beta rays.

4. Finally, the best evidence of the therapeutic value of radium is obtainable from clinical experience. Radium constitutes probably the best modern treatment for lupus vulgaris. Contrast, for instance, apparent cicatrization in seven weeks, as in reported Case III, of an extensive lupus, with a probable four to six months' duration of treatment by roentgenization, and of one to two years in the instance of the Finsen light. Finally, it is the writer's belief that the rapid, aggressive, fulminating action of pure radium bromide applied to the treatment of superficial cancer (or by embedding in other selected cases) and to the treatment of lupus vulgaris constitutes a distinct advance in the treatment of these diseases.

Equipment.—My equipment consists of Lieber's aluminum tubes containing respectively ten milligrams each of pure radium bromide as made by Dr. Sthamer of Germany, of an estimated radioactivity of 1,800,000. These tubes may be used singly or may be combined to produce a total effect. The penetrating power of the gamma rays from this equipment is remarkable. An electrode may be discharged while six inches of iron intervenes between it and them. Suspended one foot away from a pistol or rifle containing cartridges, the penetration is sufficient to exhibit in the customary manner of a skiagraph and with good definition, the cartridges within the weapon. Placed upon a block of stone one foot in diameter the rays penetrate the stone and produce an excellent skiagraphic image of objects placed upon the plate and beneath the stone. One of these tubes placed upon the skin during twenty minutes produces a radium burn appearing within from four to fourteen days and usually proceeding to a secondary stage of serous exudation.

In addition to the above, I use numerous tubes of lower and of different radioactivity and also celluloid rods and disks made after the method of Hugo Lieber of New York, from which are certainly obtained the beta rays and undoubtedly also the alpha, since the radium is spread as a thin film upon the surface of the rod and covered with the thinnest layer of specially prepared collodion.

Technique.—The methods of application of radium must, of course, vary to some extent by reason of the varied types and stages of cancer, but in general treatment is carried out, first, by the gradual method of frequent consecutive sittings of short duration and extending over several weeks or months of time; or secondly, by an aggressive and rapid attack in from one to four or six sittings, of from twenty minutes up to one hour or more each, according to clinical experience. In the latter case the operator expects to produce a severe radium burn, but the sound tissue heals with excellent cosmetic results, while the cancerous tissue (rodent ulcer type and superficial face cancer) disappears. Sound or healthy tissue is certainly far less affected by radium than is cancerous tissue. As pointed out by Prof. von Eyden in relation to trypsin, "the most marked feature of a cancerous tumor is that it re-

*Read at the Second International Congress of Physiotherapy, held at Rome, Italy, October 13-16, 1907.

sponds by increased growth to all forms of mechanical or chemical injury, or injury by heat hitherto known, but never has a tumor, after partial dissolution of its cells by trypsin, subsequently reacted by increased growth, either locally or general." The same remark I believe to be absolutely true as regards the influence of radium. It evokes no increased growth as would an irritant. Whatever gain is accomplished remains secured.

My ordinary method of application is to introduce the aluminum tube within a very thin gelatin tube such as is used to shield thermometers and which may be bought in quantity at a trifling expense. Thus every single application has its individual uninfected shield, which is then thrown away. The tube thus arranged is laid directly upon the spot which it is desired to treat and left there a certain number of minutes determined by prior clinical experience.

I have long advocated and practised in selected cases the method of embedding radium tubes within the cancer and have embedded radium contained both in glass tubes and in aluminum tubes secondarily enclosed in celluloid tubes. I puncture the tumor with a knife or with a Keyes' cutaneous punch. This instrument removes a core as for microscopic examination. Into the tubular cavity I insert the tube. Owing to the extreme hardness of certain carcinomatous masses this procedure is superior to simple incision, since the tube occupies a pocket without possible pressure and consequent irritation. Often the aluminum or glass tube is provided with a silver shield covering one side of it, thus protecting the overlying skin and parts not diseased. In this manner very severe radiation treatment may be administered to large tumor masses or even to enlarged lymph glands and recurrent nodules without fear of skin dermatitis. Since the epidermis and derma absorb perhaps one-half of the radiant energy of the radium, many tumors beneath the skin escape its full influence when employed from the outside, but by means of this method of embedding the radium tube the entire energy of the radium is available. The beneficent influence of the method is illustrated by Case I, in which a large spindle-celled sarcoma of the upper arm appears to-day to be cured as a result of two months of internal radiotherapy initiated more than two years ago.

Furthermore, and incidentally, I use radioactive water which is made by a process I have described in the *Journal of Advanced Therapeutics*, October, 1905. The emanation dissolved in the water travels in the blood stream and diffuses the transformation products of radium.

I should add, also, that I invariably administer to my patients an aqueous solution of fluorescin, or of esculin, or of quinine, in order to excite these fluids to fluoresce within the cancerous tissue during the radium treatment. Experiment admits of no doubt that these fluids do fluoresce in tissue in dilutions possible to obtain most safely by oral administrations. These views have been fully published in an article entitled "Fluorescence Artificially Produced in the Human Organism," published in the *Journal of the American Medical Association*, April 1, 1905.

Satisfactory work can, however, be accomplished only by the pure radium salt, and this fact should at once be recognized, for these salts when impure absorb, as by a sort of screen, by reason of impurities within their own mass, much of the radiation desirable for treatment. When pure, the alpha, beta, and gamma rays are obtained in their greatest quantity and at their highest efficiency. An exception to this remark may be made in the case of the embedding tubes where 100 milligrams of 20,000 radioactivity does good work. And by the use of the aforementioned gelatin and celluloid tubes and shields one-quarter of an inch in diameter and from six to ten inches long, the cavities of the mouth, throat, vagina, uterus, rectum, and the interior of ulcers and sinuses may be treated in a manner impossible by the use of the *x*-ray.

A few cases briefly reported will serve to illustrate the foregoing remarks.

Case I.—Large sarcoma of the upper arm treated by an embedded radium tube and fluorescence. Remains apparently cured now at the end of two years. Miss Lilly V., age 22, May 17, 1905. Referred by Dr. Wm. Kemble, Kingston, N. Y., with the following brief report: "In May, 1905, I examined the right arm of Miss Lilly V. and found a mass of diseased bone which I curetted out and of which I had a specimen examined under the microscope. The tissues examined showed the tumor to be sarcoma." The slides for Dr. Kemble were made in the pathological laboratory of the New York Post-Graduate Medical School and submitted to Dr. H. T. Brooks, who reports that "they show histological features of sarcoma of spindle-cell variety."

The tumor was fusiform and occupied the upper third of the humerus. It was four inches in length and two and one-half in width at its greatest diameter. Following two operations a large opening remained from which issued daily a continuous discharge of about a tablespoonful of pus. The patient had emaciated rapidly and lost her appetite. She presented the appearance of extreme cachexia. Her complexion had assumed a sallow and yellowish color. No hope whatever was entertained of saving her life, but as affording her at least a chance it was proposed to her to amputate the arm at the shoulder. This both she and her mother refused. The bone had undergone spontaneous fracture at the central portions of the tumor and required a splint for support. The case certainly seemed hopeless, but from previous experience in embedding radium I concluded to insert a glass tube into the central portion of the disease. This was comparatively easy owing to the fact that a large opening existed into its center allowing the introduction of the index finger freely and requiring packing. I accordingly placed the patient in the New York Post-Graduate Hospital and inserted the tube, allowing it to remain there continuously for ten weeks. The radium employed was the French chloride of 20,000 radioactivity, 100 milligrams. At the same time, by the way of fluorescent treatment, the patient was given six drops three times daily of a 1 to 30 aqueous solution of fluorescin and four grains of bisulphate of quinine daily. Also she took radioactive water prepared by a process I have already fully described. Beyond this she received no medication whatever nor any other treatment, such as the *x*-ray.

After insertion of the tube a skiagraph was taken and indicated beautifully the head of the humerus, the extent of the sarcomatous tumor, the fracture of the humerus in the center of the tumor, the glass tube containing the radium, and even the radium as it appeared in the tube. (See Figs. 1 and 2.) Within ten days after the insertion of the radium there was great diminution in the discharge and at the same time the pain which had been somewhat severe had entirely ceased. Within four weeks the patient was enabled to dispense with the splint which she had worn continuously with bandages and was able to move the arm somewhat freely, and moreover had regained sufficient strength to walk about a little. Within a period of two weeks she had gained seven pounds in weight and her cachectic

appearance began to disappear. She was discharged from the hospital July 21, 1905, and had gained during this time seventeen pounds in weight. The radium tube was removed and the patient allowed to return home. During the treatment there was evidence of a radium dermatitis upon the external skin, due to radiation outward of the radium.

Fig. 1.—Miss L. V. (Case 1). Showing insertion and imbedding of a radium tube within a spindle-celled sarcoma of the arm. Skiagraph taken at the beginning of treatment.

At the end of three months the patient returned for examination. The wound was nearly healed and the arm looked so well that the patient was sent back home again without further treatment. The opening closed in March, 1906. The arm has never given her any trouble since that time. She uses it as freely as ever for all purposes of life. She can use it to sweep and to do heavy work. She has gained more than thirty pounds in weight and looks to be in the perfection of health. By palpation the bone of the arm is excessively hard and presents a knob-like feeling resembling in fact a large callus. A final skiagraph was taken July, 1907, and seems to indicate that the site of the sarcomatous tumor is now composed wholly of osseous reparative material. (See Fig. 3.) It will thus be seen that a patient who was near to death and whose only hope, that was practically a small hope, was amputation at the shoulder, is now, at the end of two years, in perfect health and with a perfect arm except for a callus-like deformity. It is never safe for many years to say the word cure in a case of cancer, but we can at least say that the patient's life has been saved for the present and that the sarcoma appears to be cured to date. It is my opinion that it is permanently cured.*

Case II.—Carcinomatous tumor at knee. Mr. W. D. C., age 51, April 16, 1907. Referred by Dr. Wm. Kemble, Kingston, N. Y. Twenty-five years ago the right knee was accidentally cut with a hatchet just over the knee cap and at the site of the present disease. Two years ago was kicked by a horse on the same spot. Four months ago noticed swelling at the point of injury. After submitting to salve and iodine treatments at the hands of several physicians, visited Dr. Kemble, who removed as much as possible of the growth, which by this time was about the size of a hen's egg and flatly diffused. Microscopical examination by Dr. H. T. Brooks of the Post-Graduate Medical School and Hospital revealed the "structure of endothelioma," etc. Dr. Kemble's idea in referring the case was to cure if possible those portions of the disease which he had been unable to remove by the knife. As a result of the operation three weeks prior there existed upon the knee a cicatrix about six inches long from the lower border of the knee cap upward, and beneath this an opening. Into the opening I inserted a glass tube containing 100 milligrams of Curie radium, 10,000 radioactivity, and administered at the same time fluorescin, aqueous solution 1 part to 30, six drops three times daily. I then took a skiagraph (Fig. 4) of the radium tube *in situ*. The patient made continuous and rapid improvement. He gained eleven pounds in weight, his knee was relieved from pain, and gradually grew more flexible.

On June 1, since the entire wound had healed and all signs of inflammation and disease had subsided, I removed the radium tube embedded within the flesh above the knee by a fresh incision and placed high power radium, 1,800,000 radioactivity, within the wound for fifteen minutes to prevent soiling of the tissue by any posible disease which might remain. Patient discharged apparently well. This case illustrates the method of embedding glass radium tubes within cancerous tissue and also illustrates the effect of low power radium in causing a healing effect upon cancerous tissue.*

Case III.—Lupus vulgaris. P. N. G., age 56. The patient, a prominent physician, came under my care May 25, 1907. He had suffered from lupus for twenty-one years. The entire left side of the nose up to the bone of the bridge of the nose had been destroyed, leaving an unsightly cavity, to conceal which he wore a false nose. The edges of the gaping wound were actively diseased, ulcerated, and

Fig. 2.—Same as Fig. 1. Skiagraph taken one month after treatment was begun.

*October 25, 1907. The patient remains in perfect health, has perfect use of her arm and has recently married.

*October 25, 1907. The patient is perfectly well and attending to his usual avocation.

discharging. The upper lip on the left side was tumefied and diseased. Isolated tubercles of lupus existed on the cheek and near the inner canthus of the eye. I will give the account of his treatment in his own words: "Treatment consisted of the application, on May 25, of ten milligrams of pure radium bromide enclosed in an aluminum tube for one hour on the tip of the nose. On May 27, of twenty milligrams, two tubes on the tip and on ala nasi for four hours. On the 28th, of twenty milligrams on the septum, a part of the upper lip, and where the ala nasi joins the cheek, for four hours. Total, fifty milligrams for nine hours in three applications. The entire open area treated was irregular in shape and would aggregate about one square inch. During the first week there was not much change noticeable except that the open areas were a little more active than usual. There was no pain or discomfort whatever. During the second week there was a more decided increase in the symptoms. The sloughing became more active in the diseased areas and there was a large amount of watery exudation which soon dried and formed heavy crusts over the entire area where the skin had sloughed. These crusts had to be removed several times daily. The open sores or sloughs increased somewhat in size but all were very shallow. During this week very little discomfort was experienced. Early in the third week the symptoms increased in severity, the upper lip was swollen to almost twice its natural size, but there was little or no swelling elsewhere. The entire diseased area where the radium was applied became quite sore and painful. This was especially marked on the tip of the nose and where the septum joins the lip. The physical and nervous exhaustion was intense, with marked mental depression. The sloughing and watery exudation began to diminish in certain places. During the fourth week the swelling of the upper lip

Fig. 3.—Same patient as shown in Fig. 1. Skiagraph taken two years after the treatment.

began to subside, but the area around and beneath the eye and the upper part of the nose, which had not been treated by the radium, began to swell and became quite sore. For a few days the eyelids were swollen until they were almost closed. The discomfort here was equal to that previously experienced in the area upon which the radium tubes directly rested. There were a number of small lumps or elevations in this area, some as large as a pinhead and some larger. They became inflamed and very soon the slough below extended upward to the inner canthus of the eye and cleaned out all the lumps or

Fig. 4.—Mr. W. D. C. (Case 2). Showing radium tube permanently inserted within the cancerous mass of the knee.

swellings just mentioned. During the latter part of this week the swelling and all other symptoms began to subside very rapidly and healing began in all parts and made rapnd progress. The physical and nervous depression rapidly gave way to conditions just the opposite, and instead of the despondency was buoyancy and a sense of extreme happiness. At the latter part of the fifth week all parts were healing rapidly and cicatrization was nearly complete. The swelling in all parts had entirely subsided and no discomfort whatever was experienced. At no time did inflammation extend to tissues which had never been invaded. This would indicate to me that radium has an elective action on the tissues. The cosmetic effect in this case has been remarkably good. At no time was the suffering sufficient to prevent my attending to my professional duties."

The doctor adds in a special note: "I have wondered if there could be any toxic condition or a toxemia produced by the destruction of diseased tissues in this case. In no other way can I account for the depressing conditions mentioned. Please let me know when to come on to let you see this wonderful and rapid result. To me, this is the most wonderful thing I have ever seen. It appears to be almost miraculous. Never before have I had such remarkable results in the twenty-one years I have had the disease. I am sure you will be very proud of your work when you see these results."

July 15. Examined at the end of the seventh week, the condition was as follows: Complete and characteristic parchment-like cicatrization of all the parts previously involved by the disease. Where formerly the tissue from the inner canthus of the left eye to the opening of the nose was occupied by tuberculous lupus, there is now a clean, white cicatricial patch. This is equally true of the parts of the upper lip involved, also of the rim of the exca-

vation which had been cut into the contour of the nose on the left side. As a matter of fact, the disease appears at present completely cured. Patient returns home with this advice, to watch for any point of recurrence, and if such points become established to return for treatment.*

Case IV.—Lupus vulgaris. Mr. M. M. C., age 68, June 14, 1904. Referred by Dr. R. Tusting, Asbury Park, N. J. Began sixteen years ago. Used many remedies. Examination. Left side of the face, small, characteristic cicatrix of lupus one-half inch in diameter, one inch from outer canthus of the eye. On cheek beneath the eye, an ulcerated patch one inch long, half an inch wide, extending to within one-eighth of an inch of the edge of the lower lid. Lid congested and also eyeball, with slight eversion of the lid. On the right side of the cheek below the outer corner of the eye extending downward about an inch and extending across cheek is an irregular line about half an inch wide and for the distance of one and one-half inches was a spot considerably ulcerated but having healed areas. The ulcerating portions were discharging pretty freely. Applied radium, 1,000,000 radioactivity, irregularly, owing to the patient living at a distance, up to September 30, 1904, thirty-six times. Within a few days the discharges ceased and irritation was relieved and the ulcers began to heal. By July 11 cicatrization beneath the left eye was so extensive as to cause great eversion of the lid.

July 28. All ulcerations had healed and patient returned home to await events.

September 30. Returns with slight recurrence on both cheeks, which were immediately treated in the same manner.

December 5, 1905. Patient returns for treatment about every two weeks. There still remain two hard, little, tender spots of active lupus, but all ulcerations are healed.

Up to June 25, 1907, over a period of three years, patient has received about 160 total radium treatments. The improvement in facial appearance is remarkable and the radium has cured an extensive area which had been a distress to him for at least twelve years. The case illustrates the slow method of using radium. I believe the rapid method to be preferable.

Case V.—Lupus vulgaris. Mrs. H. H., age 59, May 18, 1905. Referred by Dr. A. R. Stern. Patient first noticed, about ten years ago, a small pimple on the left side of the nose at the junction of the cheek. This was curetted by a prominent practitioner and healed perfectly, leaving, however, an unsightly scar. Present trouble is a similar spot on the cheek about half an inch in diameter, resembling a digital depression. Palpation shows an evident falling in of the tissue and lack of substance.

Treatment.—Radium, high power, four times, thirty minutes each. Patient then went to Europe.

September 6. Patient returned, but some disease still persisted. Several more treatments of high power radium were applied until a radium burn about one inch in diameter was produced, when the patient returned to her home in Texas. On Christmas she wrote that the disease was entirely well and it has remained well ever since.

Later on, May 28, 1907, the patient returned for similar treatment for another but distant spot on the cheek. A similar radium burn was produced, and without doubt the result will be as favorable as in the first one.

*Oct. 15, 1907. This patient returns as was advised and expected for treatment of several quite small foci of disease, but the generally large area is healed and presents the usual healthy cicatrix.

Case VI.—Epithelioma of lower lip. Mr. M. K., age 66, May 19, 1905. Referred by Dr. M. D. Rushmore. Patient had been operated upon about six weeks previously with partial extirpation of diseased area of the lower lip. Disease too extensive for entire removal. Some of the affected cervical glands also had been removed, leaving others still enlarged. The induration and infiltration of the lower lip at the point of the scar was particularly well marked.

Treatment.—Radium bromide, 1,000,000 radioactivity, in an aluminum tube three times a week, half an hour at a time, two tubes, one inside the lip and the other outside. Disease went on steadily retrogressing. At the end of a month considerable dermatitis was established.

July 21, 1905. Patient discontinued treatment. The glands in the neck had entirely disappeared and also all signs of disease in the lower lip, leaving simply an ordinary cicatrix. Up to July, 1907, there had been no recurrence.

Case VII.—Epithelioma of nose. Mrs. T. R. E., age 60, March 29, 1906. Referred by Dr. Jennie E. Gore. About four years ago noticed a small, red spot on the left side of the nose which would crust over and bleed easily and would not heal. During these four years she had been to seven different physicians, who respectively prescribed zinc ointment, ichthyol ointment, "an ointment," "a wash," painting with iodine, etc., etc. Examination disclosed an open ulcer half an inch in diameter on the side of the nose, with induration at its edges and presenting a characteristic apearance of epithelioma.

Treatment.—Two aluminum tubes containing radium bromide, estimated radioactivity of 1,000,000, were laid upon the ulcer three times a week and for a period of twenty minutes at each sitting. Patient received twenty-nine treatments, extending over a period of about three months, namely, until June 1, when the ulcer was completely healed. Six months later the patient called. The original site of the wound was occupied by an almost imperceptible scar and remained perfectly sound and remains so to date. This case illustrates the gradual method of radium treatment for the ulcer continuously healed during its application.

Case VIII.—Epithelioma of lower eyelid. Mrs. H. G., age 39. Referred by Dr. F. C. Ard, Plainfield, N. J., October 6, 1902. About five years ago injured the lower eyelid by accidentally striking it against a steel towel rack. Four years ago the lid began to itch and a scab formed on it; a growth appeared and the family physician excised it. Some time after this it reappeared and extended below the margin of the lid presenting the appearance of an ulcer whose center was covered with a crust and whose margins were elevated and rounded. Was treated by curettage and applications of nitrate of silver and by a great variety of ointments, but it would not heal. Portions removed demonstrated microscopically the nature of the disease to be epithelioma. In about eighty days, with about thirty-three treatments by *x*-ray and fluorescin, the ulcer appeared to be cured and was reported by me with photographic reproduction, appearing to be a cure, in the Medical Record of May 30, 1903. Patient then went to Europe.

October, 1903. Signs of recurrence appeared in the form of a small, hard tumor at the edge of the lower lid. Low power radium was used persistently upon this and it again apparently disappeared. But again, after an interval of six months, the growth reappeared. I then concluded that the na-

ture of the disease was so obstinate that, in the interest of the patient, it would be well to excise as much as possible of the small tumor, and accordingly referred the case to Dr. Edw. L. Oatman, who at different times performed most brilliantly and successfully various plastic operations both for the removal of the cancerous tumor and the restoration of the symmetry of the lower lid. Now again, Dr. Oatman and I thought that the disease had been extirpated, but on February 14, 1907, the patient returned, exhibiting at the edge of the lid an infiltrated area whose central portion was breaking down and scabbing over and at times bleeding. Dr. Oatman says he could perform an operation, but it would be a very difficult one. In my opinion such an operation would be accompanied with grave danger of extensive recurrence. In the meantime my own experience with radium led me to believe that by using the high power radium vigorously instead of as formerly using low power, I could produce an overwhelming effect upon the tumor and rely upon its healing at the time of healing of the consequent radium burn. I accordingly gave the patient to take internally esculin and fluorescin and applied high power radium four times, twenty minutes' duration. Owing to the excessive treatment of this lid by *x*-ray and to various operations, the area was deeply sensitive to the radium application.

March 6, 1907. Lower eyelid very sore from the radium. A little tumor on the eyelid has disappeared. The hope is that the lower eyelid may now heal *pari passu* and with the healing of the radium burn. Patient again went to Europe with a fairly congested looking eyeball and with considerable redness of the lower lid, wearing a veil to conceal this.

May 27, 1907. Returns to office to report that she is perfectly well. Lower eyelid shows no signs of disease. It was a matter of great rejoicing to the patient as well as to myself to have finally apparently won out in this case. Dr. Oatman, who had performed much hard work over it, also was greatly pleased. I feel now that with high power radium at command, should the disease again occur, I have it entirely in hand.*

Case IX.—Facial cancer. Mrs. G. W. D., age 47. Referred by Dr. Francis Valk, February 13, 1907. First noticed a small scab on the cheek, one inch below the eye, about five years ago. The thickening of the skin increased in size until, at the date of examination above given, it measured three-fourths of an inch in diameter, constituting a thick plaque, raised and infiltrated at the edges and ulcerated in the middle. Treatment. Radium, highest power, ten milligrams, half an hour four times weekly.

March 6. After seven applications of radium we have an area one inch in diameter which is intensely red and in its center discharging and producing a scab, but at the same time every sign of induration and infiltration of the tumor has disappeared. The radium treatment was now arrested; the spot allowed to heal, carrying with it the healing of the cancer. A second small tumor of the lower lip was treated exactly in the same manner and the tumor entirely disappeared in about the same time. Patient at time of writing remains entirely cured.

Case X.—Epithelioma of the lower lip. Mr. F. L. H., age 45, March 1, 1907. First noticed, two years ago, a little crack in the lower lip. Soon a small lump appeared beneath it. This was excised. The wound healed promptly. Two months later it returned and was removed with "plaster." The disease has now returned, extensively involving nearly the entire lower lip. From March 1 to April 1 the patient received high power radium treatment, ten minutes daily, outside and inside the lower lip. A radium burn developed from angle to angle on the lower lip within the mouth and on the outside a similar dermatitis was established, but correspondingly all signs of tumor disappeared with the exception of a small lump, the size of a mustard grain. Radium was continued at this point daily until April 19, when the patient left for home, with no signs of disease remaining. Advised to return for further treatment should any appear.

Case XI.—Facial cancer. Mr. J. J. F., age 23, January 25, 1907. Fourteen years ago noticed a "pimple" on the right side of the nose which grew rapidly. This was lanced. It again grew and was again lanced. A lump about as big as a hazel-nut now appeared at the site of the trouble. This lump was removed by a surgeon. It recurred in three years and was again removed. It continued to recur and was removed surgically four separate times until, at the time of the present examination, a rather extensive cicatricial area existed as well as diminution of available sound skin for further operation.

Present condition. An irregular tumor mass at least an inch in diameter and raised very considerably from the surface. High power radium was applied to the tumor seven times, twenty minutes' duration, over a period of ten days. A radium burn developed two weeks later; no sign of tumor could be found; the radium burn healed kindly. Examination lately revealed no evidence of the radium burn as well as no evidence of the disease. There was left behind simply the normal cicatricial tissue due to previous operations.

Case XII.—Carcinoma of chest. Mrs. S. C. D., age 35, May 17, 1907. First noticed, eighteen months ago, a small lump the size of a hazel-nut on the left side, just above the upper edge of the left breast. This lump has steadily and slowly grown up to the present moment. During menses the tumor gets larger and itches, tingles, and prickles, and is slightly painful. The tumor mass, which measures three inches vertically by one and three-fourths inches horizontally, consists of two portions, a lower, intensely hard, disk-like mass, two and three-fourths inches in diameter, and an extending portion upward, less hard but massive. Over the disk-like mass exists a distinct depression where the skin is involved and drawn inward. For some time she had noticed quite permanently an enlarged gland the size of the end of the thumb in the left axilla. Examination reveals a very extensive network of inflamed lymphatic channels leading off toward the axilla. It was evident that most extensive infiltration of the chest wall had already occurred. It was a grave question as to what advice to give this patient and as to what to do. From my experience in such cases, I felt perfectly convinced that if operated upon the disease would recur in an extensive manner, owing to the widespread diffusion of the disease by the lymphatics. I concluded, therefore, to submit the growth to an overwhelming attack by two aluminum tubes containing ten milligrams each of radium bromide of 1,800,000 radioactivity and to push the application even at the expense of the inevitable radium burn of the skin. This plan was fully explained to the patient and her assent to the production of the burn received.

Beginning May 29, the patient received seventeen days' treatment almost daily at sittings of three hours, each of the radium tubes placed at different

*October 25, 1907. Disease still appears to be absent. For the sake of prophylaxis, one brief treatment was given.

points over the tumor mass, particularly over the disk-like depression of the scirrhus plaque. In about ten days every sign of tumor had disappeared except the plaque. At the end of the seventeenth day this scirrhus mass was reduced to a small lump about the size of the end of the little finger. The corded lymphatics could no longer be found; the axillary gland remained about as before. The skin area of the tumor presented the appearance of an intense radium burn just entering upon the serous effusion stage. The treatment was forced particularly because the patient was obliged to return to a distant State, and the result of the recovery from the radium injury and of the healing of the tumor could be awaited while at home.

The case illustrates the overwhelming attack by means of radium in contradistinction to its gradual influence, and second, the fact that an extensive and recent carcinomatous growth may quickly melt away, so to speak, under the use of radium, while at the same time a scirrhus lump has been reduced to a small mass rather soft and uncertain in feel and now about the size of a bean. Of course, the ultimate outcome of this case remains to be reported.*

Case XIII.—Carcinoma of cervix uteri. Mrs. J. F., age 64, December 5, 1906. Multipara. Referred by Dr. Wm. Kemble, Kingston, N. Y. Present trouble started in December, 1905, with a bloody discharge, which persisted up to two weeks ago, when she was operated upon by Dr. Kemble, who removed by curettage a very considerable portion of the mass of carcinomatous tissue. He then referred her to me for further cure of the disease. The aluminum radium tube, containing 10 milligrams of 1,800,000 radioactivity of pure radium bromide, was first slid into a narrow celluloid tube eight inches in length, and this in turn inserted into the patulous os, and there allowed to remain twenty minutes. Ten treatments, extending over a period of two months, were administered. At this time the os healed perfectly, and no sign of disease could be discovered. Patient returned home. By April 4 she had gained twenty pounds, and at present date, July, 1907, remains well. In this case trypsin, 20 minims up to thirty-five treatments, was also employed. I cannot, therefore, differentiate as to the relative value of these two agencies in this case. This record had no more than been made when the patient returned for further treatment for a slight recurrence.

Case XIV.—Carcinoma of uterus and adnexa. Mrs. E. M., age 59, multipara, May 18, 1907. Referred by Dr. J. N. West. First noticed, July last, quite a severe flow of blood, lasting for two days. Examined by two competent physicians from her native State. They both pronounced the trouble to be due to a very extensive carcinomatous involvement of the uterus and anterior vaginal walls, etc. Patient came to New York and went to Dr. West, who, after careful examination refused to operate because of the extent of the disease. The carcinoma had even involved the bladder. Patient cachectic, debilitated, and suffered much loss in weight. She suffers much from irritation of the bladder and with backache. There is very profuse and offensive discharge of blood and serous fluids. Examination revealed the condition as reported by Dr. West. The entire pelvic contents seemed to be caught and welded together in a solid mass, and so extensive was the carcinomatous ulceration at the cervix that an index finger could be inserted freely within the crater-like and protruding cavity. Radium tube, highest power, ten milligrams, enclosed within a celluloid tube, was inserted within the cervix, and as far upward as possible within the uterus for twenty minutes daily. Patient took 6 drops of an aqueous solution of fluorescin, one part to thirty, three times daily, and also radioactive water.

June 7. Patient examined to-day. Evidence of cicatricial action everywhere is established with retreat of the disease and a smaller area involved. The rigid and immobile carcinomatous pelvic floor has become mobile. Patient is able to dispense with half her opiates and sleeps and eats and feels much better and is in good spirits. The discharge has ceased entirely as well as the odor. The effect of the radium thus far is therefore most excellent, and the treatment will be continued.

Case XV.—Carcinoma of uterus. Mrs. E. F., age 64, multipara, May 15, 1907. Referred by Dr. Geo. W. Marshall, Milford, Del. Disease gradually developed, accompanied with pain in the back and general suffering, obliging her to take to her bed. On examination Dr. Marshall found an extensive carcinoma of the uterus involving its entire mass, and extending toward the right ovary, which was evidently the seat of cystic degeneration, for she had alternate attacks of a severe flow of blood, and then again a full flow of extremely offensive liquid filled with depressed and purulent material. Patient thin, cachectic, and feeble. Sleeps but little on account of distress and pain. The abdomen at times tumefies on the right side, and then the tumefaction disappears accompanied with an excessive discharge of offensive material. This is extremely uncomfortable until the discharge is established. I determined to use the high power radium alone in this case to test its efficacy. As in the previous case, the celluloid tube was inserted within the cervix, and even up to the fundus, and allowed to remain twenty minutes daily for one month, the patient receiving at the same time six grains of bisulphate of quinine daily and six drops of an aqueous solution one part to thirty of fluorescin, and radioactive water.

May 29. Improvement in general health and diminution of discharge and odor.

June 7. Examination. The extensive carcinomatous ulceration of the cervix had completely healed, so that the celluloid and radium tube could no longer be inserted with comfort. The tissue appeared to be perfectly sound and well. The patient reports that she is feeling very much better and that the discharges have almost ceased.

June 19. Infrequent discharge of less than half an ounce of watery fluid, with no odor and no pain, and patient is gaining in weight.

July 12. Patient returns home. No discharge whatever since two weeks. Examination reveals no signs of disease whatever. Has gained much in weight and feels perfectly well.*

The importance of the above case lies in the rapid effect upon the carcinoma of the radium, for what was visible as an extensive carcinomatous ulceration is now entirely healed, and that much progress at least has been made.

In conclusion we would submit that the pure radium salt has a decisively beneficial action in the treatment of some cases of cancer and lupus.

*October 25, 1907. Under date of October 3 the patient writes to me: "I have often thought of writing to you to tell you how very sore the radium made my breast, then I thought I would wait and write to you when it was healed. There is a small scab where the lump was that has not come off yet. I don't feel any lump there now."

*October 25, 1907. This patient returns in fine general health and has gained ten pounds in weight. But there is still evidence of disease, not extensive or troublesome, but sufficient to require treatment.

INTRACRANIAL COMPLICATIONS OF DISEASE OF THE ACCESSORY SINUSES OF THE NOSE.*

By LEWIS A. COFFIN, M.D.,

NEW YORK.

SURGEON TO THE MANHATTAN, EYE, EAR, AND THROAT HOSPITAL, FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY

In the time allotted to me this evening I shall not attempt to discuss cerebral conditions *per se,* but shall rather confine myself to the consideration of the various questions which arise from considering such conditions as related to or having their origin in the diseased accessory sinuses of the nose.

As here used, disease of the accessory sinuses of the nose means empyema of these sinuses, acute or chronic. Asked to write a paper on "Meningitis as caused by Empyema of the Accessory Sinuses," I have taken it to mean that I am asked to read a paper on the intracranial complications of sinus disease. These are the diseases of the brain due to infection. They comprise meningitis, abscess, sinus thrombosis, etc., together with the septicemias and pyemias that may arise in connection with these complications.

The existence of cerebral disease of rhinogenous origin has received scant or no attention from writers on general medicine and surgery. The subject, to say the least, has been neglected by rhinologists of this country. To those of us whose work is restricted to diseases of the nose and throat, and especially to those of us who are connected with large metropolitan clinics devoted to nasal work, disease of the accessory sinuses of the nose seems a frequent trouble. On the other hand, a vast majority of the medical profession have never given the nose or the bones entering into the base of the skull further thought than was forced upon them during their courses of study when they learned of the innumerable processes, fissures, cavities, articulations, muscular attachments, etc., connected with these bones, but never learned from any source that to any degree of frequency they might be the seat of serious disease.

Later, as hospital interne, the young medical man saw seldom, if ever, the condition of the nose or sinuses investigated during life, and it was absolutely neglected at autopsy. To the above stated facts is undoubtedly due the further fact that to a very recent date our specialty has suffered from lack of sympathy on the part of the general profession—in fact, the specialty has suffered on account of the lack of knowledge on the part of those who have entered the ranks as workers along its lines; but patient observation, investigation, exchange of ideas, recording of findings, here as elsewhere, is rewarded, and we are conscious that workers in our line have added much to the general store of scientific knowledge, as well as pointed to new ways in which life may be made more enjoyable and frequently prolonged.

One of the most interesting questions with which we have had to deal has been the diseased sinus. On general principles, we have considered its influence on the general health and comfort of our patient, its influence in the production of further nasal disease, its cause, and its eradication or cure, and in the last few years, on account of the work of many men, perhaps the most interesting question is that of the "cerebral complications of sinus disease." This phase of the subject has not received as great attention in this country as in England, France, and Germany. Berger[1], in 1886 and 1892, contributed valuable articles on the subject, and we are indebted to many men for comprehensive writings since that date—notably Dreyfuss[2], Wertheim[3], Kuhnt[4], Hajek[5], Killian[6], St. Clair Thomson[7], Logan Turner[8], and in this country Thomas Hubbard[9] of Toledo.

Since the offensive activity of the influenza bacillus in 1889—or whatever has conduced to produce the grip—disease of the accessory sinuses of the nose has been constantly on the increase and has been generally recognized, but has not been systematically studied by clinicians and pathologists. Until such scientific research has been instituted, statistics must be extremely faulty. As suggested by Turner, we shall make the mistake of overestimating the total number of reported cases if we quote the numbers given by various writers, as each reports the observations of previous authors. Therefore, in giving the authentically reported cases, I shall cite only the numbers given by the later writers who have laboriously gone over the statistics to see that cases are not repeated.

Dreyfuss, in 1896, collected and published something over fifty cases of cerebral complications having nasal origin. His classification, according to Hajek, is as follows: Arising from suppuration in the antrum of Highmore, 5 cases; in the frontal sinus, 25; in the ethmoid cells, 10; in the sphenoidal sinus, 16.

Since that time the literature on this subject has been confined for the most part by each writer to some particular sinus, or the report of cases, except for the articles by Hajek on the subject before us as connected with the sinus complex, in 1903; and later, in 1906, he has contributed a valuable article dealing with the pathology, modes, and paths of infection, etc. Logan Turner (1905), discussing the cerebral complications of frontal sinus diseases, adds 12 cases to the 30 already reported by Killian, making a total of 42. Hubbard of Toledo (1903) reported a case belonging to this class, as shown by the history and autopsy. He reports several others that might be added, but histories are not complete. From personal experience I can add but one case to this class, the history of which is as follows:

On January 13, 1905, I was asked by Dr. Frank Lewis of this city to see, with him, a woman seventy years of age who for about six months previously had noticed more or less swelling between the root of the nose and the eye of the left side. The swelling had gradually increased in size for the past three months, and had markedly increased during the past week. Aside from dull headache, she had had no marked symptoms, and had not been annoyed by nasal discharge. Friends stated that she had not been so bright as usual of late, but this was accounted for by her advancing years.

On the first visit, Dr. Lewis found a red fluctuating tumor just above the inner canthus of the left eye, but could force no pus from the lacrymal sac. The patient was sent to the Manhattan Eye and Ear and Throat Hospital, and on the following day, under ether anesthesia, an incision was made into the swelling, Dr. Lewis feeling that it was an empyema of the tear sac. A large amount of pus was evacuated—so great a quantity as to cause Dr. Lewis to feel that he had to deal with a greater reservoir than a distended tear sac, and to ask me to see the case with him, which I did on the day following

*Read at a joint meting of the Laryngological and otological sections of the N. Y. Academy of Medicine, May 29, 1907.

the operation. I found the patient conscious and rational, though rather stupid and dull. A probe introduced through the incision passed backward unobstructedly about two and a half inches, and bent, passed into the largest bony cyst of the middle turbinate that I have ever seen. I diagnosed extensive empyema of all the accessory sinuses of the left side of the head, and expressed myself as willing to operate. Fortunately, however, the operating room could not be had for several hours. In the meantime a sample of urine examined showed a large percentage of albumin and casts; the patient was reported as rapidly failing, and the idea of operation was abandoned. She died during the following night. The autopsy findings referable to the brain, as reported by Dr. E. G. Zabriskie, pathologist, were as follows:

"Incision communicates with the frontal sinus, from which pus may be seen issuing. Calvarium thickened irregularly, otherwise normal. Dura is intensely congested, distended, and firmly adherent over cribriform plate; left frontal sinus, body and wings of sphenoid bone, otherwise normal in appearance. The brain shows a diffuse purulent lepto-meningitis. Over the left convexity a greenish yellow pus is seen burrowing up between the pia arachnoid and the brain cortex. This covers the hemisphere as far back as the occiptal lobe fissures and covers almost completely the base. The outer surface of the cerebellum is only here and there streaked with purulent matter. The process seems most intense at the beginning of the Sylvian fissure, and seems to have extended upward from this point. The brain shows small patches of encephalitis, more particularly in the left frontal lobe. The ventricles are moderately distended with cloudy cerebrospinal fluid. The inner surface of the dura is everywhere smooth and glistening. On separating the dura from the skull it at once becomes apparent that at the point where it is most firmly adherent the bone is necrotic. The cribriform plate and the inner bony wall of the frontal sinus have been entirely absorbed in the process of necrosis, and instead of bone the dura—enormously thickened and covered with unhealthy exuberant granulation tissue—serves to separate these cavities from the brain. The cerebral surface of the dura at this point is normal in appearance. The ethmoid cells are the seat of intense inflammation, purulent in character, with necrosis and absorption of the bony walls. The body of the sphenoid is dark greenish in color, dry and necrotic. The sinus is filled with mucopus, and the posterior wall is remarkably thin from the necrosis.

Microscopical.—Portions of the thickened dura were cut and stained. The sections showed necrotic granulation tissue shading off into very dense connective tissue hyperplasia, which in turn resembled normal dura as the inner surface was approached. The meningeal vessels at this point seemed more congested, showed perivascular round-celled infiltration, and in many instances extensive arteriofibrosis. Bacteria could not be demonstrated penetrating the tissue. The brain, excepting for capillary congestion and small localized areas of encephalitis in the frontal lobes, with low grade chromatolysis in the outer ganglion cells, was normal."

Scholle reports two cases of meningitis due to disease of the frontal sinus, as shown by autopsy—the first, in a boy ten years of age; the second, in a girl twelve years of age. In the latter case the sinus disease was a complication of scarlet fever.

Reinhard reports a case of brain abscess and extensive leptomeningitis in a patient twenty-six years old, resulting from frontal sinus abscess.

Dr. Richard Mills Pearce reported in the Journal of the Boston Society of Medical Sciences, in 1898, the result of the examination of fifty cases which came to autopsy at the Boston City Hospital on account of diphtheria and scarlet fever. All except three were children. Of the children, all but two (one ten, the other twelve years of age) were between the ages of two and six years. The disease classification was: Diphtheria, thirty-nine cases; diphtheria and scarlet fever, five cases; diphtheria and measles, two cases; scarlet fever, forty-six cases. Sinus disease was found in twenty-five of the thirty-nine cases of diphtheria, in both the cases in which diphtheria was complicated by measles, in two of the five cases of diphtheria and scarlet fever, and in all of the scarlet fever cases.

Dr. Norval Pierce, in a paper entitled "Indications for Radical Operation on the Nasal Accessory Sinuses," states that experience teaches us that "the mortality of the accessory sinus suppurations at the present time has been greatly increased by operative interference." Although I shall return to the discussion of this statement later, I have introduced it at this place to say that I could add many cases of cerebral complications of empyema of the frontal sinus if I were to report all the post operative cases of which I have knowledge. But there is in many post-operative cases an element of doubt as to whether the cerebral complications were induced by the operative interference. This is especially so in that class of cases that die in from two to four or more weeks after operation. None of this class are referred to in this paper. Of course one's patient may die after an operation without the result casting reflection on either method or operator. For instance, suppose one had operated on the case just reported by me, he could have been certain that his operation had in no way caused the death of the patient. Further, the work of some men is among a class of patients who do not seek medical or surgical aid until great destruction of tissue has taken place or serious complications have ensued, and of necessity their mortality statistics must run higher than those of men whose work is among a better class, who seek aid at the first departure from normal conditions. Without doubt this explains to a certain extent the varying mortality results of frontal sinus work.

Sphenoidal Sinus.—The most recent and interesting article on the cerebral complications of sphenoidal sinus disease is by Dr. St. Clair Thomson, in which he has added two cases to the forty he had been able to collect up to that time. Dr. Thomson, under the heading of "remarks" says that evidence demonstrating the possibility of cerebral infection from sphenoidal suppuration is of recent date. Less than twenty years ago the very extensive researches of Berger and Tyrmann only revealed one case. Dr. Thomson, after excluding all those cases showing only ophthalmic complications—in fact, all cases not resulting fatally—as said before, found forty cases which he has arranged chronologically according to cerebral complications, in an appendix to his paper. With the two reported by himself, the classification is as follows: Meningitis, 17 cases; thrombosis of cavernous sinus, 4; thrombosis and meningitis, 13; encysted abscess of dura mater, 1; abscess, intracranial, 1; meningeal septicemia, 2; hemorrhagic encephalitis, 1; phlebitis of cavernous sinus (giving rise to pyemia), 1; intracranial hemorrhage, 1; suppurative encephalitis, 1.

Of the bacteriology, Dr. Thomson says: "In several observations the infecting organism has been demonstrated. Pure cultures of strepococci have

been found in the sphenoidal sinus and in the thrombosis of the cavernous sinus, and in the pus at the base of the brain. Staphylococci have been found in the sphenoidal sinus and in the blood in pure culture in both situations. Micrococci have been found in the blood removed by lumbar puncture, grouped in pairs, and in diplococci or in chains, in the pus of the sphenoidal sinus. The pneumococcus of Friedlander may occur in pure culture; the pneumococcus occurs in the pus of the sphenoidal sinus and in the meninges. In one case the diplococci pneumoniæ were found not only in the sinus and meninges but also in the sphenoidal bone itself, and in another the streptothrix was obtained in the meningeal pus.

On treatment, Dr. Thomson says that our knowledge justifies us in advising any patient with pus in the sphenoidal sinus to have the orifice enlarged and the sinus drained both for a relief and cure of the suppuration, and as a preventitive of ocular complications. He further states that whereas secondary infection may be ascribed to surgical traumatism, it may also be simply coincident.

So excellent and convincing is Dr. Thomson's paper that it calls forth more than a page editorial in the *British Medical Journal*. I quote two paragraphs from that editorial, as follows: "If the nose, however, has lost its prestige as a subsidiary part of the cerebral mechanism, it has in these latter days acquired a new importance as a possible starting point of suppurative processes that may extend into the interior of the skull, setting up most formidable complications. The knowledge of this particular correlation between the nose and the brain is one of the most recent advances in pathology; and as it has clinical applications of great interest and importance it is well worth while to give a brief exposition of what is known of the subject."

"How is it that this promising corner of the field of inquiry has almost escaped the searchlight of the pathologist? Three causes may be suggested: In the first place, the detection of pus in the accessory sinuses of the nose is not an easy matter and is still limited to the practice of experts; secondly, these sinuses are not regularly and methodically examined at all post-mortem examinations; and thirdly, it has not been realized that infection may pass from these air cells of the face to the cranial contents and traverse the bone without leaving any visible track or connection."

At no better place can I relate the post-mortem findings of a case which came into my hands while making a study of the development of the accessory sinuses of the nose. This case interested me so much that I got histories from two hospitals in which the child had lately been a patient, as well as a report from the mother of the child's condition during the three weeks she was at home before being taken to the second hospital.

G. E., aged nine, was admitted to Riverside Hospital, March 5, 1904, with measles. Nothing unusual is noted on the hospital records except that the nose was frequently irrigated. On the tenth of March, five days after admission, she vomited all night. On the 14th, there was bloody sputum and vomiting. 15th, restless during the night, and on the two following days was nauseated, after which she seemed to be better, and was discharged on April 6. Enlarged glands were noted, also pain in ear and lowered hearing, but no aural discharge. She was admitted to Bellevue Hospital May 2. On the admission chart the following notes appear: Well nourished and developed. Moderately anemic; very irritable; mind clear. Eyes: Slight ptosis, left; pupils equally and moderately dilated. Ears: Hearing slightly diminished; same both sides; slight tenderness over mastoids; no discharge. Nose: Normal; no discharge. Pulse: 130, regular; fair size; good force. Heart normal. Lungs normal. Abdomen: Walls held rigid. Reflexes: Patellar, much diminished; superficial, present; poorly marked double Kocnig; no Babinski present.

Spine: Rigid; no episthotonos.

Remarks: The day following her discharge from the Riverside Hospital she vomited, and for one week following was languid and lay about the house, spending most of the time in bed. For the two weeks following, seemed better, until three days ago, when she began to vomit without apparent reason, and the same morning complained of pain in the back and head. The following day the same symptoms continued, and yesterday the child complained of a painful and stiff neck.

May 3. Continues very irritable; vomits frequently after ingestion of food. Temperature remains high. Dullness, increased fremitus, bronchial breathing and voice over right upper lobe. Meningeal symptoms present.

May 5. Yesterday about 3 c.c. of clear serum obtained by lumbar puncture. Examination of same to date shows no organisms. The history shows that ice cap was kept to cervical region until death; also that irritability and nausea continued, and that delirium was intermittent, and that chest conditions developed during the four days she was in the hospital. She died on May 6.

Autopsy shows red and gray hepatization of the right upper lobe of the lung; brain is reported normal except for moderate congestion of the cortical vessels. The following anatomical diagnosis is made: Lobar pneumonia; acute parenchymatous degeneration of the kidneys; cardiac valvular lesions.

The sinuses of the head had not been explored, but on opening the same I found the left frontal sinus and the anterior ethmoidal cells of that side, as well as the antrum of Highmore, filled with pus. The os planum has just necrosed through into the orbit.

This case proves nothing, but it compels one to wish that there had been a microscopical examination and report of the brain and meninges. It shows also that the autopsy should have been carried further.

Of the clinical symptoms, I wish simply to mention that the nose was reported normal, while this child suffered from as large a bunch of adenoids as I have ever seen.

Dr. Thomson, in his classification of cerebral complications of spenoidal disease reports two cases of meningeal septicemia. This title is given by Toubert [10] to cases where the anatomical changes are trifling or even entirely absent, and where cerebral death is due to sphenoidal affection—death coming on rapidly in from two to seven days. Toubert refers to cases reported by Rouge and Weichselbaum. These patients all died suddenly after short illnesses, presenting marked cerebral symptoms. On autopsy, no pathological lesions could be found. Toubert calls it meningeal septicemia, comparing it to the peritoneal and pleural septicemias without lesions. It is not stated in this report whether the negative findings were macroscopical or microscopical. These cases may present a type of cellular meningitis, in which the changes may not be grossly evident.

In this connection I shall report the case of a boy who came to my clinic at the Manhattan Eye, Ear and Throat Hospital in 1903.

W. C., aged 9, came into the Eye Department of the Manhattan Eye, Ea. and Throat Hospital, in the latter part of April, 1903, on account of extreme swelling of the upper lid of the right eye. On the next visit there was decided exophthalmos. The case was referred to me and was diagnosed as empyema of the ethmoid cells, and ordered ready for operation. The tumor ruptured between the eye and the nose while an anteoperative bichloride pad was *in situ*. After ordinary incision and evacuation, the pus was found to be coming through an opening in the os planum. This opening was enlarged downward along the side of the nose, and the entire ethmoid tract, including the sphenoid, was curetted. The eye receded immediately after the operation and the boy was discharged, well, on July 1. In November following, he was again brought to the hospital, with the left eye affected in the same manner as the right had been. In the meantime my statement that I had curetted out the spenoid sinus of this boy had been questioned. It was said that children of nine years had no sphenoidal sinus. So at the second operation I was more cautious than during the first, and contented myself with curetting out the ethmoid, stopping—as was shown by autopsy—at the anterior wall of the sphenoid. The eye did not recede as before, the temperature remained up. Seventy-two hours after this operation, the boy, having shown during this time marked cerebral symptoms—was found unexpectedly dead in bed. On autopsy no apparent cause of death was found. The sphenoidal sinus was well developed and full of pus. No microscopical examination of the meninges or brain was made. I have always felt that this patient died—not because of the operation, but because the operation was not sufficiently radical.

If Toubert's meningeal septicemia will stand, I think I can add this case to those reported by Rougé and Weichselbaum.

Bergengrün[11] reports the death of a patient 28 years old five hours after the opening of the frontal sinus, which was found not to be diseased; but autopsy disclosed disease of the ethmoidal and sphenoidal cells complicated by diffuse meningitis and thrombosis of the cavernous sinus.

Dr. J. H. Bryan has reported a case dying of acute leptomeningitis on the fourth day after operation. Autopsy showed a diseased sphenoidal sinus which had not been opened. Dr. Bryan expressed the feeling that had the operation been carried into the sphenoid the patient might not have died.

McCaw in 1905 reported a meningitis complicating suppuration in the ethmoid cells. Complete autopsy was not done.

Dr. E. Gruening of this city in 1904 reported an interesting case of extensive brain abscess, complicating ethmoiditis, demonstrated at operation. Pneumococci were found in the pus taken from the nose, orbit, ethmoids, and brain. An autopsy was not made, therefore the condition of the sphenoid was not reported.

Stanley Brown, Pathologist to Queen's Hospital, Birmingham, in 1905 reported a case of meningitis complicating a pan sinusitis on which no further operation had been done than an exploration as to the condition of the dura back of the ear and a lumbar puncture. The latter showed the spinal fluid to be turbid and yellow. Patient died on the following day.

Although I believe in the independent existence of ethmoidal disease, I have never seen cerebral complications accompanying such disease. Dreyfuss, however, collected 10 cases.

Such are the clinical evidences of the correlation of empyema of the accessory sinuses of the nose and the various infectious diseases of the brain, more or less supported by pathological and bacteriological study. The whole atmosphere of one who studies the subject is full of interrogation points. My belief is that disease of the accessory sinuses—singly or conjointly—is far more prevalent than is generally thought, even by those whose work is confined to the nose. This belief is supported by the post-mortem findings, as cited by Dr. Thomson, of Harke, E. Fraenkel, Lapelle and Marten, and Kicer, —which showed sinus disease in 30 per cent. of all subjects coming to the dead house; and T. S. Kirkland of Sidney found sinus disease in 11 out of 22 subjects (50 per cent.) who had died of pneumonia. In this series, while disease was found in one or more sinuses of each case, it was always found in the sphenoidal. These figures would seem to be at variance with those of Pitt, quoted by Pierce. Pitt's figures are useless in this connection except as they show that up to 1888 the condition of the accessory sinuses were seldom if ever investigated, either before or after death. He collected records of 9,000 deaths, with especial reference to meningitis and brain abscess. He reports a certain number of cases of meningitis as due to ear disease; a certain number due to disease of the bones of the skull (these, I take it, are sinus cases); and one case of nasal origin; a case of polypus—a case probably so self-evident as to make investigation imperative.

From all later investigations one can see that the importance of the subject before us has been more and more impressed upon investigators; and more and more are the conditions of the accessory sinuses being investigated by both clinicians and pathologists.

Relative frequency.—As to the relative frequency with which disease of the various sinuses is transmitted to the brain, there is not yet enough satisfactory evidence on which to form a positive opinion. It is a peculiar coincidence that Thomson in his article dealing with the cerebral complications of sphenoidal sinus disease was able to report the same number of cases as Turner, who was discussing the same condition from frontal sinus disease—42 in each case. However, I am of the opinion that when the evidence is all in, the sphenoidal sinus will be considerably in the lead.

1. Its anatomical structure and relations are such that it would seem that disease would be transmitted more easily and therefore more frequently from it to the brain than from the frontal sinus.

2. It is present, on the average, in the individual seven years previous to the frontal sinus.

3. Its disease is diagnosed with less ease than is disease of the frontal sinus, and therefore to date probably more cases have been overlooked.

Turner says: "We have not here (in studying cerebral complications of sinus disease) the same data to reason from as in the ear, and that comparison between the relative frequency of the occurrence of endocranial complications following aural and nasal suppurations is hardly feasible . . . . and further: All observers will, I think, agree in saying that suppurative middle ear disease is a much more common affection than suppuration in the nasal accessory sinuses. This will still be admitted, even if we exclude the large number of children amongst whom ear suppuration is so prevalent—a group of patients which cannot fairly be used for comparisan, because in them the nasal sinuses have not yet fully developed." Now I shall

raise no question with Dr. Turner on the relative frequency, but I do not question his reason.

In the class of children to which he refers, the air cavities of neither ear nor nose are fully developed, and to the extent that they lack full development are they more liable to disease. The only sinus lacking in a child one year of age is the frontal. The ethmoids are present at birth, and the sphenoid appears soon after, and I feel certain that more frequently disease of these cavities exists in young children than is generally believed. I see no reason why we should not look here for the explanation of some of our numerous cases of so-called idiopathic meningitis, of which there were reported in this city nearly 200 during 1906—of whom 75 were under one year, and 135 under five years of age. This, perhaps, is too speculative for place in this paper, but disease of the pneumatic cavities of the head in young children, and the possible correlation of this disease with intracranial trouble, has been of great interest to me for several years, and I look to further investigation for light on the subject.

Kirkland reported disease of the sphenoid at three years of age; Dr. Bardes, of this city, has reported disease of the same sinus in two cases aged respectively 5 and 6 years, in which the disease was demonstrated once by autopsy and once by operation—the one coming to autopsy having died from meningitis following operation on the ethmoids, the sphenoid not having been reached. The first patient died, Dr. Bardes believes, because the sphenoid was not operated. Disease of sphenoid was demonstrated by operation in the second case and prompt recovery followed.

Careful investigation by the sympathetic cooperation of the clinician and pathologist is time consuming and expensive. However, the subject is of such scientific interest, both academically and practically, that we may confidently expect more certain and convincing findings in the near future.

I am unable intelligently to discuss the question of modes and paths of the transmission of the infection from the various sinuses to the brain. These are academic questions and belong to the pathologist, from whom we shall welcome the solution. We know, of course, that the transmission must be direct from sinus to brain along blood-vessels, or indirectly through the blood or lymph channels. I see no reason why it should not be in any or all of these ways, and for all practical purposes it makes but little difference.

As to why one person suffering from disease of one or more sinuses should develop cerebral symptoms and lesions, while another should not, is a question of interest. Zarniko[12] in discussing this question says (1) it may be on account of gaps in the bony walls which separate the accessory sinuses from the cranial cavity. (2) It may be due to stagnation of the secretion in the accessory sinuses due to strictures or obstructions of the passage leading into the nose—further remarking that while it would be a mistake to deny the importance of this factor, its overestimation should be borne in mind, as in a number of cases extension of infection from the sinus to the brain was demonstrated, notwithstanding the fact that a perfectly free communication of the diseased sinus with the main cavity of the nose was established. (3) It may be on account of the specific or especially virulent infectious agents.

Again, an interesting question is—What effect has the chronicity of a diseased sinus in producing cerebral lesion?

Evidence seems to point to the fact that the same rule holds in disease of the sinus as holds in the ear—namely, that the greatest danger is in a severe acute infection, or in an acute exacerbation of a chronic disease; and on the proper appreciation of these conditions must depend the treatment instituted. Unfortunately, bacterial findings of secretions taken from the nose or from the sinuses through their natural openings, on account of the almost certain contamination, are of little or no value. One's course must be guided by the subjective and objective symptoms presented in any individual case, together with such evidence as may be obtained from transillumination, skiagraphy, washing of sinus, etc.

So far as cerebral symptoms and disease are concerned, the treatment must be prophylactic; as to the diseased sinus, treatment may be preventive or curative.

However marked, cerebral symptoms may be relieved if no further change has taken place in the brain than congestion or a serous exudate, resulting in a so-called serous-meningitis. The following history is of interest.

F. C., Swede, female, aged 20. Came into my clinic at the Manhattan Eye, Ear and Throat Hospital, January 11, 1905, on account of severe frontal and occipital headaches which had troubled her more or less during the last four years. She complained also of a frequent bloody discharge from the right nostril. Intranasal examination showed a large middle turbinate, and pus could be seen in the middle and superior meatii of the right side. Some ptosis of the right upper lid was evident. Temperature normal. Frontal and ethomidal sinusitis was diagnosed, and a conservative plan of treatment was instituted, consisting of cocaine and adrenalin sprays and steam inhalation. For a day or two the symptoms seemed to be somewhat relieved, but on January 14, three days after admission, all symptoms became worse, and on the evening of that day I was notified by telephone that the temperature was 103°, the disks were choked, and the patient had vomited all ingested food. I ordered the patient ready for operation and at 9 o'clock that evening did a Killian operation for relief of the frontal sinus disease. The recovery was prompt. This is an instance in which marked cerebral symptoms were relieved by operation.

Turner was able to collect about 24 deaths from cerebral complications following operation on the frontal sinus. There are two classes of case following operation for the relief of suppurations of the accessory sinuses—those which are due to well marked cerebral lesions during the first day or two, and those which die in from two to four or more weeks after the operation,—the latter class being due probably to faulty operation, either through undue traumatism or the stirring up to pernicious activity of a latent infective agent in some diseased sinus or part neither recognized nor invaded at the time of operation. On such a case Pearce evidently based his paper in which he states that "the mortality of accessory sinus suppurations at the present time has been greatly increased by operative interference." A more correct statement, I think, would be that the apparent mortality from accessory sinus suppurations is greatly increased since the more frequent diagnosis of disease of these cavities. Many deaths have occurred as the result of operation, but the blame should be placed where it belongs—upon those operators who are willing to undertake so difficult, complex, and serious an operation without being sufficiently educated and prepared for the work.

In order to find some backing for the above state-

ment, I am able to report the mortality statistics from accessory sinus operations of a few men whom I have known as doing good sinus work.

Our distinguished visitor, Dr. Killian, tells me that he has operated radically for the relief of disease of the frontal ethmoidal and sphenoidal sinuses 100 times, with three deaths. Four other men here to-night have operated 240 times with three deaths, one of which I have reported to-night. Of the other two deaths, one occurred on the table from the anesthetic, and the other from pneumonia, two months after operation.

Undoubtedly as good a showing from much larger figures might be obtained from the statistics of many more men, but these I think will show that cerebral complication from operative interference is not a frequent occurrence at the hands of men who are doing the greatest amount of such work; and further, that if Pierce's statement be correct, then when such complications do occur, the operator cannot hold himself blameless.

What seems to the writer an extremely good suggestion is made by Stanley Brown, to wit, that in all cases of sinusitis showing marked cerebral symptoms a lumbar puncture shall be made to the end that those cases showing a thick and definitely yellow spinal fluid shall not be operated on, as we may safely assume under such circumstances the presence of a septic meningitis, and an operation which may be in many cases the only means of saving life will not needlessly be brought into discredit. A cloudy fluid does not contraindicate operation. The unaided eye may be depended on, and therefore the operation need not be delayed.

PHOTOTHERAPY IN NEURITIS.

By A. D. ROCKWELL, M.D.,

NEW YORK.

NEUROLOGIST AND ELECTROTHERAPEUTIST TO THE FLUSHING HOSPITAL, ETC.

In admitting the altogether unsatisfactory results following the ordinary and accepted methods of treatment for neuritis, a distinguished neurologist once asked me as to my experience in the treatment of this condition by physical methods in general, and electricity in particular. I, too, was compelled to admit that with this latter agent my own experience had not only been far from satisfactory in a curative way, but that not infrequently in both acute and subacute cases of neuritis there would result a distinct aggravation of symptoms. The use of the static spark in the treatment of acute neuritis on the theory that it overcomes blood stasis, and thus relieves pressure, is most fallacious. It may, indeed, overcome blood stasis, but it overcomes it at the expense of infinite damage to the sensitive nerve. The faradic current is equally useless, although not equally harmful, while vibrating methods, so valuable in many conditions, are also futile as well as harmful.

High frequency currents I have thoroughly tested, and have also found wanting here.

The galvanic current has proved more satisfactory in my own hands than any other modality, but the benefits following its use are not usually great, and, unless much care is exercised in its administration, it, too, may aggravate the symptoms.

I am well aware that different views are held by many enthusiasts in electrotherapeutics, but a somewhat varied experience in both hospital and private practice, and with every kind of electricity in neuritis, is my justification for these opinions. Pain, indeed, in many forms is often relievable, and even curable, by electricity, as has been abundantly demonstrated, but not the pain of acute neuritis.

In phototherapy we have a method of treatment, which, theoretically, is well adapted for the relief of pain dependent on congested and inflammatory conditions, even though deep-seated, and practically I have found the light treatment to be far more efficacious in neuritis than any other therapeutic measure. By phototherapy is meant light treatment, and yet not light alone—for an incandescent light of 500-candlepower yields not only an intense light, but powerful heat and efficient chemical rays as well.

The ten cases of neuritis that follow I believe to be of real clinical value from the fact that they are not selected cases, but include all that came under my observation during the past winter, with the exception of two that received but one and three exposures, respectively, before abandoning treatment.*

Case I.—Mrs. T., age 45; referred to me by Dr. Byron V. Tompkins of this city, December 3, 1866. Neuritis of the left arm since February, 1905, which she attributed to sitting for hours every day with the arm next to the window, while decorating china. She had been subjected to much treatment, including vigorous counterirritation, but with no avail. The applications of light and heat were administered three times a week, and from the first resulted in immediate relief. This relief would continue for several hours, when the pain would return, and she would suffer quite as much as before. The relief, however, soon became more prolonged, and the recurrent pain less severe, so that after a few weeks of the treatment the applications were reduced to two, and finally to one, a week. She was enabled to use her arm with much of the old freedom, and after three months of treatment she ceased her visits, feeling that she was approximately well. Subsequently she wrote me that in packing to go away for the summer she wrenched her arm several times, exciting considerable pain, showing that the cure was not even yet complete, and might require further treatment on her return.

Case II.—Mr. J. S., age 47; referred to me by Dr. Z. L. Leonard of New York, December 31, 1906. Dating from a violent strain nine years previously, this patient had complained of an almost continuous sensory disturbance in the right thigh, extending in less degree to the calf of the leg. When quiescent he was but little annoyed, but on exercise much pain was excited, and in the language of the patient "the parts became hot, as if a hot iron was pressed upon the skin," and disturbed him to such an extent as to interfere with his ability to take much if any exercise. The constant pain had so impaired the nutrition of the thigh that it had decreased in circumference one and a half inches. High frequency currents were first attempted in this case, but after a few applications, as no benefit followed, the treatment by phototherapy was substituted. The first application seemed to give a certain measure of relief, and the relief became very positively evident after a few additional treatments. When urgent business took him abroad, after having been under observation about two months, he was not altogether free from his chronic disturbing symptoms, but so very much better that they annoyed him but little, and he was enabled to exercise with comparative freedom.

Case III.—Mr. P., age 28; referred by Dr. Frederick Knowles of New York, January 12, 1907. This patient was a good deal of an athlete, and in one of his sports a year previously had violently strained his right leg. The symptoms following were of gradual development, and consisted of pain in the lower part of the back, the hip, along the course of the sciatic nerve, and extending to the calf of the leg and ankle. Associated with the sharp and shooting pain, he soon began to experience a sensation of heat and burning throughout the whole limb, which gradually increased in severity, and finally quite overshadowed all other symptoms. The right thigh measured one inch less than its fellow, and the calf of the leg half an inch, showing a considerable impairment of nutrition.

The lower portion of the back and hip, and the entire length of the leg, were submitted to the light rays, each seance lasting some twenty minutes, and repeated from three to five times a week. There was manifest improvement from the beginning, and, when the patient found it necessary to go abroad after less than two months of treatment, all the burning symptoms and the pain had disappeared, and he considered himself entirely well.

Case IV.—In a case of sciatica, referred by Dr. A. R. Carman, February 8, 1907, the results were unsatisfactory, but it is possible that the failure was due, not so much to the inefficiency of the remedy as to the methods of the patient himself. He was a man of 60, and had suffered since the previous summer from severe pains, most pronounced in the calf and hips. From February 8 to 22 fourteen exposures were given to the point of extreme redness and slight perspiration of the limb, and at first with decided temporary relief. Subsequently the patient failed to get relief, saying that sometimes he felt rather worse after reaching home. He would attend regularly to business, traveled miles to the office, rain or shine, using the street cars, and refusing to take an automobile, which he could well afford to do. Undoubtedly the exercise and strain of coming and going had much to do with the unsuccessful result in this case.

Case V.—Miss G., age 39, came to me March 2, 1907, with this history. Some six months before, while lying in a hammock, the rope broke and she fell upon her back. Fortunately she was but a few inches from the ground, but the blow was sufficient to cause excessive pain and a slight temporary paralysis of the limbs. Since that time she had suffered constantly from radiating pains near the juncture of the dorsal and lumbar vertebræ, which those whom she had consulted had variously termed rachialgia and spinal irritation. My own judgment was that her persistent pains were due to some traumatism, or chronic congestion at least, of the posterior nerve roots. Electricity had been used, and she had been blistered and subjected to the actual cautery. The latter alone had afforded her relief, and this was but temporary and slight. She was subjected to the effects of the light and radiant heat rays, with the result of exciting almost immediate perspiration and a complete relief from all pain. The pain returned in a few hours in about the same degree as before, but every exposure resulted in the same relief, with increasingly longer intervals, until she entirely recovered, having been under treatment two months with twenty-nine exposures.

Case VI.—Mr. F., age 38, was referred to me March 25, 1907, by Dr. José F. de Fernandez of this city. Five months before he had an attack of grip. From this he quite recovered, but there remained a painful right arm and shoulder, which gradually grew worse. Early in February a second attack of grip prostrated him, confining him to his bed for two weeks. The pain in the arm now grew worse and became continuous, whereas before the second attack it was intermittent. The whole arm suffered, but the pain at times was most intense in the index and middle fingers, indicating that the musculo spiral was implicated. The pain was so severe that on several occasions hypodermics were resorted to for relief. He had before this used the static spark and breeze, the faradic and galvanic currents; and perhaps the most interesting and instructive portion of Dr. Fernandez's report of the case was in regard to his previous experience in the use of the different electric modalities. The static spark, the static

*For the principles on which is based the use of phototherapy in diseases, the reader is referred to my article on Phototherapy in Nervous Diseases, Medical Record, March 27, 1897.

breeze and the faradic current seemed to accentuate rather than relieve the pain. The galvanic current relieved temporarily only. The treatment by phototherapy resulted in immediate relief. After each of the first five treatments the hand and fingers, which naturally showed temporary congestion, remained in a swollen condition for hours, but after the fifth exposure the swelling subsided in a comparatively short time. Treatment was administered three times a week, each seance lasting from 15 to 20 minutes. During the six weeks that the patient was under treatment there was steady progress up to final and complete recovery.

Case VII.—Mr. G., age 33, referred by Dr. M. R. Alvarez, April 27, 1907, had been suffering almost constantly from pain in the left arm from the shoulder to the wrist since the middle of February of the present year. There had been no initial constitutional disturbance of any kind, and the attack following loss of sleep and exposure, seemed to be of the chronic type from the beginning. There was but slight tenderness on pressure along the course of the main nerve, but pronounced hyperesthesia of all the finger tips of the affected hand and distinct fibrillar twitchings in the muscles. The static spark had been attempted on two or three occasions, but with disastrous results. The first application of light and heat to the affected arm was continued to the point of deep redness and profuse perspiration. This was repeated daily for a week, when the patient reported much less pain, very little tenderness on pressure, and less sensitiveness of the finger tips. At the end of six weeks, after fifteen exposures, there was hardly a trace of the old trouble.

Case VIII.—Mrs. D., aged 60; referred by Dr. W. M. Stone of Flushing, L. I., May 6, 1907. Eighteen months before she was prostrated by grip, followed by an attack of neuritis in the left arm. This persisted for many months without abatement, but finally the symptoms became less severe, although even yet there were some traces remaining. Her present condition was one of severe and quite constant pain of the face and head, which extended deep into the ear. The scalp and face were tender to pressure, and the symptoms had persistently resisted the various efforts made for their relief. In this case the results of treatment were unusually rapid and satisfactory. The five exposures that were given completely and permanently dissipated all pain and tenderness.

Case IX.—Dr. McC., aged 60 of this city consulted me June 30, 1907. Two months previously, on awakening, he found that motion caused much pain in the left shoulder and arm. Soon the pain became constant, even when the arm was at rest. He knew of no cause for it, but thinks he must have strained it during sleep, as on awakening he found his arm under his body and somewhat twisted. Static electricity had been tried, as well as vibration, but with no result, and fourteen light treatments proved equally unavailing.

A druggist told him how much a capsicum plaster had accomplished in a certain "similar" case, and it was decided to drop the treatment and try the simple cure. Some weeks later he wrote: "The capsicum plaster failed miserably. From what my friends in the profession tell me of their experience with this trouble, and I have heard a lot, I believe the thing just comes and goes without any specific time limit, and without being affected by treatment. Recently my friend, Dr. ——, dropped in to see me, and described my symptoms exactly in telling of his own experience some years ago. He had 'tried' everything. It lasted from August to late November and then went away. The last things he remembers trying were stimulating liniments and gentle motion to toleration. I have adopted these measures, and shall continue them and trust to luck."

Case X.—Dr. M., aged 55, a practitioner of this city. Five years previously I had treated this patient successfully with massive doses of the galvanic current for acute paroxysmal pains due to traumatic causes that for more than a year had resisted every effort for their relief. It had been a most extraordinary case and was subsequently published in detail.*

He now consulted me a second time (May 20, 1907) for a constant pain in the neighborhood of the second dorsal vertebra, associated with a sense of constriction on bending forward. If excited either mentally or physically, this sensation developed into a terrific pain, accompanied by increased heart action, and as the pain extended to the solar plexus it would seem to indicate sympathetic involvement.

As the galvanic current had before relieved symptoms even more severe than those from which the patient now suffered, it would in all probability have relieved him again. The patient concurring, however, phototherapy was substituted, and with results both immediate and permanent that were most gratifying. At the end of six weeks, having received fifteen treatments, he left town for the summer with but slight symptoms remaining, and on his return reports that his condition still remains good.

Thus it is seen that out of ten consecutive cases of neuritis, eight experienced more or less immediate relief with ultimate recovery.

In Case IV. there was temporary relief in the beginning only, but the failure in this case is partly accounted for by the impossibility of getting the patient to exercise due caution in the matter of exercise. The ninth case was an unmistakable failure, for which an explanation is wanting. It was not necessarily because the cause was possibly traumatic, for other traumatic cases had promptly recovered. The inefficiency of the remedy in this case was more likely due to some constantly operating defect of metabolism, unresponsive to physical methods of treatment.

In conclusion, it may be said that phototherapy is by no means confined to neuritis or nervous diseases. In addition to its power to relieve blood pressure and pain, its bactericidal properties, its influence as a promoter of tissue metabolism, and its power to increase the hemoglobin-carrying power of the red corpuscles, render it of value in a variety of constitutional conditions.

Blackening of the Tongue from Peroxide of Hydrogen.—Bizard recently called the attention of the Paris Society of Medicine to the causes of blackened tongue and reported that he had recently seen this effect produced in two syphilitic patients under his care who were treated with injections of gray oil and mouth washes of a solution of peroxide of hydrogen. It might have been supposed that the peroxide of hydrogen on coming into contact with the saliva of the mercurialized patients gave rise to a reaction which produced a brown coloration of the extremities of the lingual papillæ, but the fact was that peroxide of hydrogen might by itself cause blackening of the tongue. In a man habitually enjoying good health, not syphilitic, and free from constitutional defects, but a smoker and the subject of hypertrophy of the lingual papillæ, the daily use of a gargle of peroxide of hydrogen in half a tumblerful of warm water produced in eight days a very pronounced blackening of the dorsal aspect of the tongue. This disappeared in a few days when the peroxide of hydrogen was stopped and the surface of the tongue soon afterwards desquamated in large flakes.—*The Lancet.*

MEDICAL RECORD.

ELECTRIC NARCOSIS.

A well-known electrotherapist to whom the remark was made a short time ago that electricity was still in its infancy, made reply that he did not agree with the statement, as he thought that electricity was now a remarkably well-grown and lusty child; in fact, quite past the infantile stage. There is no doubt that in the region of electrotherapy immense strides have been made, and although there must be room for great advance in this direction, it can but be said that this branch of medical science is in a very healthy condition.

On February 27 of this year, Dr. M. Stephane Leduc of Nantes announced in *La Presse Médicale* the results of experiments he had been pursuing in regard to the production of electric narcosis. Considering the high standing of Dr. Leduc and the great importance of the statements made by him, it is somewhat extraordinary to notice with what slight attention his paper has been regarded in medical journals, both in this country and in Great Britain. In view of the supreme interest of the matter from a medical standpoint, it may not be out of place to note briefly the main features of Dr. Leduc's article.

In the first place, he explains that he means by the term electric narcosis a state analogous to chloroform narcosis, a state in which the subject is without power of voluntary movement, makes no reply to stimulation, and exhibits only some reflex movements, such as the beating of the heart and respiration; he further declares that this state, produced by the action on the brain of a definite electric current, can be maintained for several consecutive hours, and ceases immediately with stoppage of the current. According to the author, in order to induce electric narcosis, the circuit is formed by the supply, the rheostat, the interrupter, the current reverser, the milliampèremeter, and the subject. The hair is shaved from the head of the animal to be experimented on, dog or rabbit. The hair should be shaved off close and the skin must not be cut. The shaven surface must extend in front to the eyes, so that all the anterior part of the brain is traversed by the current and under its influence. On the shaven surface is placed a thick piece of absorbent cotton, soaked with a hot 1 per cent. solution of sodium chloride. On this is placed a pliable tin electrode, to which is soldered the conducting wire. The second electrode must be much larger, and must be placed on any point of the body, so long as it is symmetrically placed in the axis. All the accessory apparatuses are placed between the supply and the large electrode on the back, which is connected with the positive pole. The head electrode must be connected directly with the negative pole. By this means the potential of the head remains always that of the negative pole of the supply. When the experiment is properly carried out, the animal passes quietly and gradually, without a cry, without a defensive movement, and without a sign of pain, into a state of cerebral inhibition analogous to chloroform narcosis. The experiment can be stopped instantly by cutting off the current. The awakening is instantaneous; usually the animal gets on its feet, looks quietly round, shows no sign of suffering, fright, or fatigue, and when released from the electrodes jumps about gaily and eats with appetite food offered to it. There are no after-effects, no vomiting, rarely a little stupor. The experiment seems to cause no pain, for the animals not only do not show it, but evince no resentment, no aversion toward the experimenters, no fear, and no revolt during preparations for another application. As Dr. Leduc truly says, this is all the more remarkable in the dog, which can so well recognize friend and foe. Experiments with animals were in a high degree successful, the narcosis having been kept up for long periods without injury to the animals. Dr. Louise Robinovitch of New York, who assisted Dr. Leduc in some of his experiments, kept a rabbit in electric narcosis for eight hours and twenty minutes without interruption. The animal came to without displaying discomfort. Dr. Robinovitch studied the temperature of animals during electric narcosis and concluded that it was more often than not under normal.

Up to the present time only one experiment on cerebral inhibition has been done on man, and that was on Dr. Leduc himself, in the presence of Malherbe and Rouxeau of the School of Medicine of Nantes. In this instance the current was not raised sufficiently high to cause total unconsciousness, but the experiment was carried far enough to convince the operators that if necessary this could have been done. The current was raised to 35 volts and 4 milliampères in the interrupted current. Altogether Dr. Leduc was under the influence of the current for five minutes; he felt no after-effects, unless we count as such a sense of well-being and physical vigor, and immediately after he went and lectured before the Société de Retraite Ouvrière.

The result of these experiments would seem to teach that electric narcosis is well within the province of practical medicine, and to demonstrate the value of the interrupted current. Dr. Leduc is said to be convinced that the production of electric narcosis in man is but a question of time. It remains to find out what is the limit of safety, that is to say, to what height the current may be raised to produce general anesthesia without danger to life. Judging from the experiments on animals, there should be no great danger to man in experimenting with the interrupted current in the hands of experts. The advantages of electric narcosis over anesthesia produced by the usual agents appear to be obvious. The lack of unpleasant after-effects and the length of time during which animals can be kept in a state of unconsciousness are sufficient to recommend the method. Of course, the reports may, and

probably are, somewhat unduly eulogistic as to the merits of electric narcosis, but at any rate this mode of producing anesthesia is worthy of consideration and discussion. That the value of the interrupted current has been overlooked seems also to be more or less apparent.

THE ROLE OF RATS AND FLEAS IN THE DISSEMINATION OF PLAGUE.

For a long time little was known concerning the way in which the plague spread through a city or was carried from country to country, but finally its diffusion was connected with rats, the latter now being generally conceded to be the essential factor in the diffusion of the disease. Naturally, with a disease of such high mortality, a study of its mode of spread and of its prevention is of the greatest importance.

In a report to the Fourteenth International Congress of Hygiene and Demography, Dr. J. A. Thompson, Chief of the Department of Public Health of New South Wales, set forth his views on this subject, basing them on a careful study of the plague epidemic in Sydney, among civilized people and under circumstances in which particulars concerning the infection of the individuals attacked could be learned with accuracy. He found that the fundamental question as to the share taken by the sick in diffusing the infection remained unsolved. In the first epidemic of 303 cases, he had a complete history of 289 patients, 276 of whom occupied dwellings widely separated from each other; in 266 of the latter only a single case occurred, although the greater majority had lain at home three days before being reported. Ten houses harbored multiple cases, which he divided into several groups; in the first, the time of onset of the successive cases was almost simultaneous; in the second, twenty-two or more days elapsed after cleansing before a second patient was taken ill; in the third group, the time relations of the successive cases were such that communication from primary patients was possible. In the first two groups, exposure of both of the infected members of each household to the same conditions appears to have been the determining factor; the cases in the third group really also admit this explanation when we consider that in 266 households no secondary cases occurred. Two other observations which bear on the question of communication from the sick were made. Total want of connection between successive cases in the same house was most often established with certainty, and the interval between them was often much longer than the incubation period. All this evidence, according to Thompson, warrants the formulation of the general rule that the epidemic spread of plague occurs independently of communication of the infection from the sick and it spreads by means which are external to man. Plague pneumonia furnishes a conspicuous exception to the general rule, but this is now relatively uncommon.

The author found that associated cases and those in dwellings far distant from each other had a sole distinguishable bond, which consisted in their resort during the day to the same workplace, to which they did not return after the onset of illness. Consequently it then fell to be inquired in what the infectiousness of locality consisted. He noticed that a very short line of wharves at which the produce trade (grain, hay, chaff, potatoes, etc.) was carried on had always been the immediate source of the local infection, and all the subepidemics began either at produce stores or at stables to which the produce had been carried from the neighborhood. The infection would manifest itself in new areas which were separated by wide tracts of plague-free houses. By such observations attention was forcibly directed to some animal which was free to wander among the dwellings of man, but which had access to the interior of only some of them. From antiquity it had been observed that rats sometimes died in numbers in places where man died of plague. In 1894, the disease in the rat was found to be the same as in man, and the rat was found to be the only animal in which epizoötic plague existed and which was close to man. Thompson therefore tried to establish some closer association between plague rats and cases. During an epidemic of twelve cases in nine buildings, seven of which were in a central district and two far away, plague rats were found in each; in other houses plague rats were also found, but no cases. These three widely-separated districts were, however, connected in the following way: Materials which experience had shown to be specially dangerous in connection with the introduction of plague into clean places, namely, hay, chaff, grain, etc., were conveyed from one of the first-mentioned seven houses to the two at a distance. All this goes to prove that epidemic dissemination of the infection is effected by the rat, but it does not explain the communication from rat to man.

The facts that the handling of dead plague rats by man was rarely followed by infection, that it was often possible to exclude contact or even close neighborhood between rat and man infected with plague, that plague rats were found in forty dwellings, in only four of which plague in man was found, go to show that the disease is probably not directly communicated from rat to man. The most generally received opinion is that the infection is conveyed to man by inoculation, the uninjured skin being an efficient defence against infection. Infection by inhalation or by feeding is rare. In the majority of cases Thompson found buboes in the groin, and just as frequently in people wearing shoes as in unshod people, so that the infection could not be attributed to wounds of undefended feet. He found that people who were fully clothed, having only their arms, face, and hands uncovered, were infected in the protected parts, as buboes in the groin were most frequent. Inoculation must have been effected by some agent which could penetrate both clothing and skin. The flea alone answered these requirements; moreover, within buildings fleas live in the dust between flooring boards, outside in the soil, and notoriously reach the legs first. He therefore concludes that the flea is the ordinary agent of infection, and it, as well as the rat, is indispensable to produce epidemics.

Thus the measures which must be followed to prevent or check plague should be directed against the rat and the flea. Even though his experiences furnish no evidence which points to the transfer-

ence of the infection from the sick to man, he advises isolation of the patient. Prevention of epidemic plague lies mainly in habitually maintaining a distance between rat and man, for measures directed against the flea can have scope only in special circumstances. The requisite separation between man and rat will be better secured by improving the construction of buildings than by attempts to exterminate the rat. Complete rat destruction is difficult, and as only a few rats are affected in a rat epidemic, the plague rats may not be caught at all, as a sick animal usually remains in its nest. The danger to man from plague is directly proportionate to the accessibility of the interior of buildings to rats, and as experience has shown the difficulty with which all rats are killed in a building, the rational method of defence lies in so improving the construction of buildings as greatly to impede the entrance of rats to them, and in so taking care of food that it shall not attract them. When plague rats have been found in a dwelling, the first thing to be done, according to Thompson, is to spray the floors freely with a 5 per cent. solution of carbolic acid. This is a very effectual method of driving away and killing fleas, and thus of avoiding the only risk connected with the cleansing of plague-infected houses.

Although nothing absolutely new regarding plague and its mode of dissemination is offered in this address, the contribution is nevertheless one of great value. It affords most positive evidence of the fact of a double epidemic, one of rats and the other of man, running parallel one to the other, the inter- and intracommunication being maintained through the agency of the flea, although this does not necessarily preclude direct infection from rat to rat, and from man to man. The author implies that an epidemic of plague is entirely controllable, and this is doubtless the case in places such as Sydney or San Francisco, where the authority of the health officer can be exercised without fear of revolt; but the conditions in Calcutta and Bombay are very different, for the passive resistance or open hostility of the native population is something that must be reckoned with and that often ties the hands of the most efficient of sanitarians.

The Causation of Appendicitis.

Among the many etiological factors that have been suggested as underlying the inflammatory affections of the appendix, none has as yet seemed to be consistently applicable, and not a few—such as bicycle riding, strap hanging, chronic antimony poisoning from rubber stoppers of bottles, the ingestion of particles of steel from the rollers of flour mills, etc. —may be criticised in much less measured terms. Constipation is often alleged as being at least a predisposing factor, but the explanations of the manner in which it is supposed to act have not been altogether acceptable. For example, the natives of Turkey, Asia Minor, and the adjoining countries are very subject to constipation, and yet appendicitis is almost unknown among them. Naab (*Münchener medizinische Wochenschrift*, October 15, 1907), in describing his experiences during a number of years' residence in these Eastern countries, emphasizes the freedom of the Orientals from appendicitis. Out of 6,800 patients coming under his observation in Mesopotamia, only two suffered from the disease, and a colleague, practising in a neighboring district, during five years, also encountered only two cases. In Constantinople the conditions are somewhat different, owing to the more mixed character of the population. In the two large native hospitals the morbidity from appendicitis is .18 per cent. and .3 per cent., respectively, while in the German hospital of that city, in which the patients are almost exclusively white persons, the proportion jumps to 2.6 per cent. From the standpoint of operation the conditions are somewhat similar, and of 1,000 operations, including numerous laparotomies, performed annually by three white surgeons in three regions of Turkey in Asia, only one was for appendicitis. In the Turkish hospital in Constantinople the operations for appendicitis are only .3 per cent. of the major operations, whereas this proportion is increased more than ten times in the German hospital of the same city. In spite of the rarity of inflammatory conditions of the caput coli among his Oriental patients, Naab found that they were very prone to constipation, so that he regards this factor alone as inadequate to cause appendicitis. On the other hand, he calls attention to the almost exclusively vegetable diet used by these people, and offers the suggestion—which has been made before—that it is the excessive meat consumption of the white races that causes them to lead in the statistics of appendical disease. The constipation due to excessive meat eating leads to the stagnation of small, hard scybala, which are caught by the rugosities of the colon and large intestine, and give rise to local irritation of the mucous membrane, while, with a preponderatingly vegetable diet the fecal masses are much larger and there is less tendency to stagnation through intestinal inactivity. Naab, furthermore, points out that the increased consumption of meat in Germany has been attended by a considerable increase in morbidity from appendicitis, and considers that the relationship between meat eating and the disease is unmistakable. His contribution will no doubt be read with pleasure and referred to with enthusiasm by the vegetarians, but the last word on the etiology of appendicitis has not been spoken yet.

Tuberculosis of the Testicle.

Tuberculosis of the testicle is rarely or never a primary affection, being usually incidental to tuberculosis in other organs. It is observed most commonly between the twentieth and thirty-fifth years of life, and, as a rule, both organs are affected, simultaneously or successively. Sometimes extension takes place from the kidney, while less commonly the testicle is involved first, and the kidney secondarily. In the way of diagnosis simple epididymitis, syphilis, and new growths must be taken into consideration. Death seldom or never occurs as the result of the disease of the testicle. The treatment is hygienic and surgical. The latter includes evacuation of hydrocele, at times with injection of an irritant chemical, such as carbolic acid; incision, drainage, and curetting of abscess and fistula; erosion; orchidectomy; epididymectomy. An interesting study of the subject has been made by Dr. E. L. Keyes, Jr., in the *Annals of Surgery* for June, 1907, based on observations on 100 patients, of whom 53 presented involvement of both testicles. From this it appears that testicular tuberculosis is clinically never an isolated lesion. It is only one feature of a general genital tuberculosis. Sterility is frequently, if not constantly present at the time the first testicle is invaded. At this time evidence of inflammation of the internal genital organs can be

found if looked for. Development of disease in the opposite testicle occurs within a few years, in eight or nine cases out of ten, and such occurrence is in no wise deferred by early removal of the diseased testicle. Suppuration seems often to result in a permanent cure of the local process, and a chronic focus several years old is likely never to suppurate, but in no case can a cure be expected to take place unless the tuberculous epididymis is removed. Castration exercises a demoralizing influence on the individual, while epididymectomy does not, and the latter is almost invariably followed by spontaneous cure of the lesion of the testicle. It is therefore the operation to be preferred, unless there is hyperacute generalized epididymoorchitis, or unless the testicle is destroyed by suppuration. It has been found that this operation also exercises a beneficial influence upon the general health and upon coincident tuberculosis of the internal genital organs. When possible, therefore, it should be performed early in the course of the disease, even though the involvement of the testicle be but an insignificant part of a generalized progressive tuberculosis, or has for many years been the only active lesion of the disease. If the patient is sterile it is probably better to remove both epididymides, even though only one is diseased.

The Benzidin Test.

The value of Schumm's benzidin reaction for the presence of blood in the stomach contents, urine, feces, etc., has been attested by numerous observers, and several modifications of the test have already been suggested, notably Einhorn's benzidin paper. One of the difficulties originally experienced in applying the reaction to the feces, namely the hypersensitiveness of the reagent, may, according to Schlesinger and Holst, be overcome by using only a few drops of a watery extract of the stool, instead of the larger quantities that were at first employed. In order to avoid error through the action of organic oxidizing ferments, the watery extract should be brought to the boiling point before the test is made. Carried out in this way, the test is suitable for clinical application with the understanding that its value is greater on the negative than on the positive side, and that in doubtful cases the resort to one of the older tests, such as Weber's, is advisable for corroboration. In a recent communication, Schumm himself, however (*Deutsche medizinische Wochenschrift*, October 17, 1907), calls attention to a feature that, for the present at least, somewhat invalidates the reaction for general application. This is the fact that he has discovered in the course of his work with the reagent that different samples from different chemical manufacturers, and even specimens obtained at different times from the same maker, exhibit unaccountable and extreme variations in sensibility to blood. In some instances the variations were so great as to render the results misleading, while in others the reagent was found wholly useless. While it is likely that improved methods of manufacture with this end in view will make it possible to secure uniformity in the quality of the chemical, for the present it must be made use of with some reserve, and new supplies must be subjected to careful control tests before being employed in routine work.

In making rectal examinations, if no finger cot is at hand, the finger may be protected by enveloping it in a piece of tissue paper, which is then plentifully smeared with

The Action of Iodine and Phosphorus upon the Thyroid Gland.

As the thyroid extract acts favorably in some cases of rachitis, in hemophilia, in hematuria, and in delayed callus formation, it is safe to suppose that it has a regulating influence in the assimilation of calcium salts. In order to prove that it has, Silvestri and Tosati (*Gazzetta degli ospedale*, No. 102, 1907) gave small doses of thyroid extract to healthy persons, all of whom were kept on the same diet before and during the ingestion of the extract. In ten cases examined the amount of calcium in the urine and feces diminished after the ingestion of the extract, the latter thus acting in cases of hemophilia, etc., by causing a retention and assimilation of the lime salts. The authors mentioned believe the amount of phosphorus and iodides in the thyroid extract is too small to attribute to these substances the action regarding calcium salts; and the known beneficial action of iodides on metabolism and blood pressure, and of phosphorus in osteomalacia and rachitis they explain by their stimulating action on the thyroid gland and not by a direct action of the drugs themselves.

A Tuberculosis Problem.

The Paris correspondent of the *Lancet* relates in the issue of September 23 the case of a man who had been for seventeen years in the service of a railway company, but had been discharged on the ground that he had tuberculosis and was not, therefore, fit to continue his work. He thereupon sued the company, and on the basis of the testimony of an expert employed by the court to ascertain the facts, he was awarded damages of 5,000 francs. It was held that his unfitness for active and regular work had not been proven because the progress of the disease from which he suffered was slow, and he was strong enough to follow his employment.

News of the Week.

International Congress on Tuberculosis.—At a meeting of the Committee of Arrangements for this Congress, held in this city on October 28, Dr. Lawrence F. Flick presided and reported on his visits to the International Conference on Tuberculosis in Vienna and to the International Congress on Hygiene and Demography in Berlin. More than a thousand delegates were registered at each of these and it is expected that about four hundred members of the foreign organization will attend the Congress to be held in Washington next year. Dr. John S. Fulton, the Secretary-General, reported that the following distinguished foreigners had consented to participate in the series of special addresses that are to form a part of the program: Dr. R. W. Philip, Edinburgh; Dr. C. Theodore Williams, London; Dr. Arthur Newsholme, Health Officer, Brighton, England; Dr. C. H. Spronck, Utrecht, Holland; Dr. Karl Turban, Davos-Platz, Switzerland; Dr. Gotthold Pannwitz, Charlottenburg; Dr. Emil von Behring, Marburg; Dr. A. Calmette, Pasteur Institute, Lille, France; Dr. Maurice Letulle, Paris; and Dr. S. Kitasato, Tokyo, Japan. Dr. Fulton also reported that up to the date of the meeting the Governors of twenty-three States had given official recognition to the Congress.

The Koch Memorial Fund.—The project of recognizing Robert Koch's scientific work by the foundation of an institute to bear his name is meet-

ing with approval and Dr. Carl Beck of this city is the American member of the committee of organization. Prince of Donnersmarck has contributed 50,000 marks and the Emperor has promised financial support.

Russell Sage Institute of Pathology.—Articles of incorporation were filed with the Secretary of State on November 1 by the Russell Sage Institute of Pathology of New York, which is to be endowed by Mrs. Sage for purposes of scientific research and the investigation of the diseases and infirmities of advanced years. Dr. Edward G. Janeway, Dr. Theodore C. Janeway, Dr. D. Bryson Delavan, Dr. Simon Flexner, and Dr. Graham Lusk are the directors.

Quarantine Against San Francisco.—The State Department has been informed through the American Minister at Christiania that the Government of Norway has declared quarantine regulations to be in force against ships arriving at Norwegian ports from San Francisco, the California port being considered as infected with Oriental plague.

Conditions at Panama.—Major J. L. Phillips, Superintendent of the United States Hospital at Ancon, who arrived here last week, gave a very favorable report of conditions in the Canal Zone. There have been no cases of yellow fever for five months and, though malaria is still rife, great progress is being made in exterminating mosquitos. The quarantine regulations are being enforced with great strictness to prevent the introduction of disease from without.

A Society for the Extermination of Rats.—As a result of the propaganda of a society in Copenhagen with the title "L'Association Internationale pour la Destruction Rationelle des Rats," the Danish legislature has passed a law providing for a systematic effort at the extermination of the rat, which is now in active operation. Under the act the State undertakes to spend $8,000 annually for three years, and compels the county and borough councils to spend 80 cents a year for each 100 inhabitants. The society has agreed to spend at least $2,500 each year for the purpose, and in return for this expenditure it is intrusted with the entire working of the act. Statistics gathered by a civil engineer named Zuschlag, who founded the society, showed that the depredations of the rodents in Denmark alone were responsible for $2,000,000 of preventable damage, without considering the possible transmission of disease by their intervention.

To Exterminate Crocodiles.—Professor Robert Koch, who is now on his way back to Berlin after a prolonged stay in East Africa for the purpose of studying the sleeping sickness, is quoted as saying that the disease is a menace to the whole of East Africa. It is transmitted by the insect *Glossina palpalis*, which derives its chief nourishment from the blood of the crocodile, and Koch accordingly recommends that efforts be made to exterminate the saurians.

To Treat Defective School Children.—Twelve physicians and a number of nurses of Pittsburg have volunteered their services to the Pittsburg Bureau of Health for the purpose of examining the pupils of the public schools, with a view to discovering any existing physical defects among them. If operative treatment is advisable, the parents of the child are to be notified and referred to their family physician. It is the intention to urge the authorities to make an appropriation for the establishment of a permanent bureau of inspection.

Public Lectures on Diet and Endurance.—Mr. Horace Fletcher and Dr. W. G. Anderson will deliver addresses open to the public at the Academy of Medicine on Thursday, November 14, 1907, at 8:30 P.M. Mr. Fletcher will speak on "Possible Progressive Growth in Muscular Efficiency After Fifty Years of Life Without Systematic Physical Exercise," and Dr. Anderson's subject will be "Observations on the Results of Tests for Physical Endurance at the Yale University Gymnasium."

Bequests to Hospitals.—Bequests to the following institutions are made by the will of the late George C. Taylor, a son of the late Moses Taylor, who died in Riverhead, R. I., last month at the age of seventy-two years: Moses Taylor Hospital, Scranton, Pa., $750,000; St. Luke's Hospital, Manhattan, $25,000; Society of the New York Hospital, $25,000; American Society for the Prevention of Cruelty to Animals, Manhattan, $50,000; New York Society for the Prevention of Cruelty to Children, $50,000; Sheltering Arms, Manhattan, $25,000; St. Mary's Free Hospital for Children, Manhattan, $25,000; Orphans' Home and Asylum for the Protestant Episcopal Church, Manhattan, $25,000; Children's Aid Society, Manhattan, $25,000; New York Association for Improving the Condition of the Poor, $25,000; Five Points House of Industry, Manhattan, $15,000; Society for the Relief of Destitute Children of Seamen, West New Brighton, $15,000; Society for the Relief of Destitute Blind, Manhattan, $25,000; Home for the Incurables, Fordham, $15,000; St. John's Guild for its Seaside Hospital, $25,000; Presbyterian Hospital, Manhattan, $25,000; Trinity Association for its Seaside Home, $25,000.

Thrall Hospital Fire.—For the second time in two months the Thrall Hospital of Middletown, N. Y., has been endangered by fire. The fire started in the sterilizing room and one nurse was badly burned about the hands and arms. The damage to the building was slight.

Fire in the Montefiore Home.—A fire in the laundry of the Montefiore Home for the Aged last week made it necessary to carry downstairs some of the feebler patients and caused considerable excitement among the inmates of the institution, but was extinguished before the main building was involved. The two-story laundry building was destroyed.

International Association of Urology.—An organization with this title was formed in Paris at an organizing meeting held on October 8. The membership of the society is to be very small and meetings will be held every three years for the purpose of discussing set themes. The presidents elected are Guyon, Israel, and Harrison. The first congress is to be held in Paris in October, 1908, under the presidency of Albarran, Posner, and Watson.

Medical Society of Virginia.—The thirty-eighth annual session of this organization will be held in Chase City, November 12 to 15, 1907, under the presidency of Dr. Paul B. Barringer of Blacksburg. The corresponding secretary is Dr. John F. Winn of Richmond.

New York and New England Association of Railway Surgeons.—This society will hold its seventeenth annual meeting at the Academy of Medicine in this city on Thursday and Friday, November 14 and 15, 1907. The president of the association is Dr. H. T. Dana of Cortland, N. Y., and the secretary Dr. Geo. Chaffee of Brooklyn.

Chicago Surgical Society.—At the annual meeting of this society, recently held, the following officers were elected for the ensuing year: *President*,

Dr. A. J. Ochsner; *Vice-President*, Dr. A. E. Halstead; *Secretary*, Dr. F. A. Besley; *Treasurer*, Dr. J. C. Hollister; *Councilor*, Dr. D. W. Graham; *Council or to Chicago Medical Society*, Dr. M. L. Harris; *Alternate Councilor*, Dr. A. D. Bevan.

Chicago Gynecological Society.—The following officers were elected for the ensuing year at a meeting of this society, held October 18: *President*, Dr. Joseph B. De Lee; *Vice-Presidents*, Dr. Chas. E. Paddock and Dr. Rudolph W. Holmes; *Secretary*, Dr. Henry F. Lewis; *Treasurer*, Dr. Chas. B. Reed; *Editor*, Dr. Frank W. Lynch; *Pathologist*, Dr. Geo. Schmauch; *Councilor*, Dr. Emil Ries.

Tuscola County (Mich.) Medical Society.—At the last meeting of this society officers were elected as follows: *President*, Dr. King of Caro; *Vice-President*, Dr. Olin of Caro; *Secretary*, Dr. Wickware of Cass City; *Treasurer*, Dr. Garvin of Millington.

Society of Railway Surgeons of the Pacific Coast.—The following were elected as officers at the fifth annual meeting of this organization, held in Los Angeles on October 21: *President*, Dr. John R. Colburn of Los Angeles; *Vice-Presidents*, Dr. G. A. White of Sacramento and Dr. F. L. Adams of Oakland; *Secretary*, Dr. J. P. Dunn of Oakland.

Hospital Conference.—At a meeting of the Hospital Conference held at the Academy of Medicine last week a resolution was passed recommending that the members of the association call the attention of their respective boards of managers to the question of the ward rate for pay patients and suggest the desirableness and fairness of increasing the rate from $1 to $1.50 a day. This would not be sufficient to cover the expense of maintaining the patients, but would tend to bring the hospital charges in accordance with the general scale of wages, which has risen considerably of late years. The rate would be merely the maximum and would be imposed only on patients able to pay it. After the meeting Dr. W. Gilman Thompson gave an illustrated lecture on modern European hospital construction.

Dr. H. W. Lincoln has been appointed Gastrologist to the Swedish Hospital of Brooklyn, N. Y.

Obituary Notes.—Dr. William Moss died on October 30 at his home in Chestnut Hill, a suburb of Philadelphia, at the age of seventy-four years. He was graduated from Jefferson Medical College in the class of 1855 and served as surgeon in the civil war.

Dr. Seth. D. Close of this city died suddenly on October 30 at the age of fifty-six years. Dr. Close was born in Geneva, N. Y., and was graduated from the College of Physicians and Surgeons in the class of 1876.

Dr. Frank Heuel of this city died on October 28 at the age of fifty-two years. He was the son of the late Dr. Frank Heuel and was born in this city. He received his medical degree from the University Medical School with the class of 1875. He had held many hospital and dispensary positions and was a member of the faculty of the university.

Dr. Charles Mohr of Philadelphia died suddenly on October 30 at the age of sixty-three years. He was born in Philadelphia and had been, until recently, Professor of Materia Medica and Therapeutics at the Hahnemann Medical College of Philadelphia. He was also general director of the Hahnemann Hospital.

Dr. H. B. Palmer of Farmington, Me., died suddenly on October 24 at the age of forty-six years. He had been ill for some days with a trifling ailment and is believed to have taken hyoscine hydrobromate, thinking it to be a preparation of aconite which he had been using.

Dr. E. S. Kimpton of Charlestown, Mass., died on October 25 at the age of fifty years. He was a native of Stanstead, P. Q., and was a graduate of the Harvard Medical School.

Dr. R. H. McMullen of Rockport, Tex., died on October 24 at the age of seventy-eight years. He was born in Fayetteville, Tenn., and began practice in Huntsville, Ala., in 1865. In 1903 he retired from active work and went to live in Rockport with his son, Dr. W. F. McMullen.

Dr. William M. Lawlor of San Francisco died on October 23 at the age of sixty-two years. Dr. Lawlor was born in Albany, N. Y., but had practised in San Francisco for many years.

Dr. George B. Hammond of Royal Oak, Mich., died on October 24 at the age of forty years. He was once Health Officer of the township and a member of the City Council.

Dr. M. B. Moon of Iowa City died on October 26 of apoplexy at the age of fifty-six years.

Dr. Linnaeus Fussell died at Media, Pa., on October 28 at the age of sixty-five years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1867.

Dr. Alexander Caldwell of Philadelphia died on November 3 at the age of sixty-three years, after a brief illness. Dr. Caldwell was a surgeon in the Tenth Missouri Regiment during the civil war and was afterward on General Grant's staff.

Dr. Edmund H. Martin of this city died on November 3, aged eighty-two years, at the home of his son-in-law, Dr. James H. Dew. Dr. Martin was born in Georgia and practised medicine in Savannah until after the war. Then he went to New Orleans, where he practised up to a few years ago, when he retired and came to New York.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

TUBERCULOSIS IN IRELAND; EXHIBITION OPENED IN DUBLIN—SESSION OF THE SOCIETIES—THE ROYAL SOCIETY OF MEDICINE AND ITS SECTIONS—CLINICAL CASES—CHANGE OF PROCEEDING IN PATHOLOGICAL SECTION—MEDICAL SOCIETY OF LONDON, PRESIDENT'S ADDRESS—MEDICAL OFFICERS' REPORT TO GOVERNMENT BOARD—OBITUARY.

London, October 18, 1907.

"I am commanded by the King to express his good wishes for the success of the Tuberculosis Exhibition, the first of the kind ever held in Great Britain and Ireland. . . . His Majesty is greatly interested in the problem of checking the progress of this disease, and trusts that the exhibition may be the means of directing the attention of the public to the terrible ravages caused by this scourge and to the efforts that are now being made to avert its progress."

The above message was received by the Lord Lieutenant of Ireland on the occasion of his opening on Saturday of the exhibition in Dublin under the auspices of the Women's National Health Association. The Countess of Aberdeen explained that the exhibition was not intended to remain in Dublin, but to go around the country, and wherever it went it would have friends ready to instruct visitors and teachers to show the exhibits representing different stages of the disease. There would also be diagrams showing that though checked in England and Scotland the disease was increasing in Ireland. Lord Aberdeen then declared the exhibition open and insisted on the importance of improving the condition of the homes of the people. Remarking on the interest of the King in the subject, he said that not long since, when in attendance on His Majesty, he had to introduce an American physician who had done splendid work on tuberculosis. The first thing the King said to that physician was, "Have you seen the sanatorium at Banchory?"

The Chief Secretary followed with a speech in which he expressed confidence in the good which would result

from the exhibition, especially if it perambulated the country, as wherever it went it would excite interest and appeal to the eye, through which all learned more than through any other channel of intelligence. He remembered fifty years ago in Liverpool that typhoid fever was looked upon as a divine institution and submitted to as a plague. Now it played no considerable part in the death rate of Liverpool; it had been got rid of by medical skill and public attention to hygiene. This scourge of consumption could be treated in the same way. The doctors had found out how it was generated, whence it came, how it was spread, and they had also hit upon expedients for curing it. They asked the people of Ireland—every one of them—to do their very best to put it down. The exhibition would be a traveling professor, instructing the people not only to realize the existence of the scourge, but to take active measures against it.

Professor Osler said this was no government battle—the work must be done by the people themselves. The Irish climate he pronounced to be a first-rate one for consumptives. It was no more moist in any part of Ireland than it was at the tail end of England, in Cornwall. You could not have a moister spot than Cornwall, and yet Cornwall had a climate in which there was no place for consumption. People said Ireland was a bad place for consumptives, but that opinion did not come from the medical profession. It was one of those fads that possibly women might have encouraged. Sunshine was not really necessary for the cure of the disease; the things that were essential were fresh air, good food, good houses, and hope.

In connection with this subject I may cite the report of the Local Government Board for Ireland, which states that in 1905 nearly 12,000 deaths were due to tuberculosis—a death rate of 2.7 per 1,000 of the population, of which 2.1 was due to pulmonary tuberculosis. The rate in Ireland is far in excess of that of either England or Scotland. In the exhibition there are four sections. The first contains diagrams, maps, and tables of statistics of tuberculosis in different countries. They show how much Ireland is behind in the fight and holding the fourth place in British possessions. While the mortality has decreased for a succession of years in England and Scotland, it has increased in Ireland. The deaths in Ireland last year from tuberculosis were much in excess of all other diseases. The second section is devoted to pathology, and models are shown of the bacilli and sections of the tuberculous organs. In other parts spitting cups, handkerchiefs, models of bungalows, screens, etc., are displayed, and there is a section devoted to the literature, which shows what has been done by municipal authorities and what medical officers of health are advocating.

After the opening of the schools comes that of the societies. Both are now at work. You will remember that a number of the societies disappear as independent organizations, being absorbed in the amalgamation with the old Medical and Chirurgical, familiarly called the "Medico-Chi." The result is that we now have the "Royal Society of Medicine" as our chief society, with a series of sections representing the several absorbed bodies. Some of these have already met. Thus on Friday the Clinical Section assembled under the presidency of Sir Thomas Barlow, who delivered an introductory address in which he outlined the history of the "Clinical Society" during the forty years of its independent existence. Naturally it is impossible to adequately review the work during such a period of a society carried on with remarkable energy and success and ever in the van of medical progress from its own standpoint.

The new section set to work in the old style by exhibiting some interesting cases. A case of congenital absence of the fibula was shown by Mr. Openshaw in a boy of ten. The outer half of the foot and the two outer toes were also absent. With an apparatus he could walk and play games. In contrast with this, Mr. Openshaw also showed a child of six months, both tibiæ being practically absent. He was against amputation in such cases. He thought the scar often seen in them was caused by intrauterine fracture of the bone. Mr. D. Drew showed a girl with a movable knee joint after two arthrectomies; also a case of congenital dislocation of patella operated on successfully. Mr. Hutchinson had just had a case of fusiform aneurysm of the right carotid. Dr. Batten showed a man of sixty-two with slight nystagmus and marked kinetic ataxia, which began six years ago and became worse three years ago. Mr. Rowntree showed a man with a myxosarcomatous growth on the thigh, and Dr. Leviand another with diffuse sarcoma. The diagnosis of this was questioned by Sir D. Duckworth, who recommended sarsaparilla. Perhaps the most interesting case was that of a woman of twenty-five with multiple nodules, shown by Dr. Garrod as of rheumatic origin. She had acute rheumatism two years previously to their development. No cardiac lesion. They had been present eighteen months—over the metacarpo-phalangeal joints, elbows, and knees of both sides, and one shoulder. Dr. S. West remarked that he had seen several cases and in some of the worst there had been no heart lesion. Sir D. Duckworth said he was familiar with such cases in adults and struck with their long duration. Dr. B. Abrahams had had four cases in adults and was skeptical as to their rheumatic nature. He had followed them for years without any sign of rheumatism appearing. Dr. Poynton had seen children with nodules of long duration. The president, Sir T. Barlow, accepted the diagnosis and had found the association of endocarditis and nodules less close in adults, in whom, too, they often lasted over a year. Mr. Steward showed a child on whom he had opened an empyema at the left base and then opened the pericardium and drained through the same wound. The pus from both was pneumococcal. Dr. West had seen recovery from an interior opening and advocated simple incision without thoracotomy. Mr. Godlee related a case successfully drained by Mr. Raymond Johnson, in which the pyopericardium followed osteomyelitis.

The Pathological Section also met on Tuesday, when the president announced an important change he was instituting in the conduct of the proceedings. Instead of a series of set speeches following a paper, he will introduce a conversational method, which he thought would prove specially adapted for their work. By this means, which may be called the Socratic method, members will ask the readers of papers questions which arise out of them and which will elucidate the subject through the explanations offered in reply. The plan is not new even in medical societies. The old "Medico-Chi" was intended to interchange knowledge by "way of easy conversation," as well as by lengthy papers, but it degenerated into a rather cold and to many formidable debate with set speeches. Perhaps other sections will follow the example of the Pathological.

The Medical Society of London is the oldest of our societies and it preserves its independence having declined to join in the amalgamation scheme. Some say there was a difficulty about its endowments, but others think the sentiment of independence and pride of seniority were the prevailing motives of its remaining separate. At any rate the vote has decided the question and we must not confuse the old Medical Society—still vigorous if not young—with the new section.

The session of this society was opened on Monday, when Dr. J. K. Fowler delivered his presidential address. This he directed to the defence of medicine against the slight which some would put upon it as less progressive than surgery. He held that medicine had kept pace during the last thirty years. Considering the advances made in that period, he claimed that, having regard to the wide field covered, medicine had made greater progress than surgery, and he believed that in the future it would far exceed the results of the past.

The report of the Medical Officer of the Local Government Board has been issued, and illustrates in various directions the value of medical inspections. Among other things, the report deals with international and imperial services rendered by the Medical Department—vaccinations, plague, cholera, cerebrospinal fever, and auxiliary investigations. Dr. Buchanan investigated the subject of the meat of pigs affected by tuberculosis. He says the present system of control in London is uncertain and unequal in operation. Moreover, it is weak in that it is primarily dependent on examination of the dressed carcass instead of the animal at the place where the internal organs can be inspected at the same time. The epidemics of typhoid fever at Basingstoke and Lincoln, accounts of which by Drs. Farrar and Reece are given, reinforce the lessons of previous occurrences, and should be carefully considered by local sanitary authorities, in relation to any development of or changes in water supply.

Dr. Harold Budgett Meakin, Surgeon to the Calcutta Hospital and Professor of Pathology at the College, died on the 21st ult. at Nordrach, where he had gone on account of tuberculosis. He was a London graduate, M.B. 1894, M.D. 1895. In 1898 he entered the Indian Medical Service, won medals and prizes at Nelley, and was appointed to the Ninth Gurkhas, with which he saw active service on the frontier. He was at the capture of Pekin and later chief of the Wei-hai-wei hospital. A man of great force of character, intellectual gifts, and artistic taste, he made friends wherever he went, who will much regret his early death. He was only thirty-seven.

Dr. P. J. O'Connor, surgeon to the liner *Fluminense*, when joining his vessel at Liverpool on the 11th inst., fell over the quay and was drowned, aged fifty-two.

Typhoid Fever.—In attempting to check the spread of a typhoid epidemic the authorities of Prague have forbidden the wearing of trailing skirts.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

STERILIZATION OF MILK—JENSEN MOUSE TUMORS—SPREAD OF TUBERCULOSIS BY BOOKS—SUICIDES AND ACCIDENTAL DEATHS IN DENMARK.

COPENHAGEN, October 6, 1907.

In the Blegdams Hospital of Copenhagen Dr. Valdemar Bie has worked out a method for the sterilization of milk, the properties of which are stated not to be altered by the procedure. In order to avoid the destruction of the enzymes of the milk and the alteration of its proteids, brought about by the ordinary pasteurization, some years ago another Dane, Mr. Budde, adopted a method, the chief feature of which was heating the milk to a temperature of 50-55° C. only, after addition of about 0.4 per mille of hydrogen peroxide. The milk being able to decompose at the mentioned temperature, the employed quantity of H_2O_2, no detrimental effect on the human organism could ensue from the addition of the disinfectant, and after heating for eight to ten hours the milk was claimed to be sterile, while a heating of two to three hours' duration enabled the milk to keep sweet for eight to fourteen days. Unfortunately the sterility of the "buddeized" milk would seem to be not always reliable, and it is, to say the least, probable that the enzymes and proteids of the milk undergo some change by the prolonged heating to 55° C. Therefore Dr. Bie heats the milk only to 35° C., a temperature absolutely harmless with regard to the mentioned substances. As, however, the milk is not in itself able to decompose at this temperature a quantity of hydrogen peroxide sufficient to insure the sterilization, he uses an extract of malt as a catalysator to decompose the surplus of peroxide. This method is as follows: After heating the milk to 35° C. he adds 1 c.c. hydrogen peroxide to 200 c.c. milk, which is subsequently placed for six hours in the incubator at 35°. After cooling down to 10° C. he adds 50 c.c. of an aqueous extract of malt to 200 c.c. milk and places the mixture in the icesafe for eighteen to twenty-four hours, when the hydrogen peroxide has entirely disappeared. The results attained are good. Ten samples of the purest raw milk obtainable in Copenhagen contained on an average 62,668 bacteria to the cubic centimeter before sterilization; after which one c.c. contained only an average of eight bacteria.

The cancer committee of the General Danish Medical Association has sent out its report, the most important item of which is a communication of Prof. C. O. Jensen, the discoverer of the mouse cancer on two typical inoculable sarcomas in the rat. He emphasizes the importance of obtaining a larger stock of inoculable tumors than has hitherto been available. Of the best known tumors, the mouse cancers, at this time hardly more than eight different samples are living in the laboratories. Spontaneously growing inoculable sarcomas have as yet not been found in mice. In rats only one instance of carcinoma allowing of transplantation is known. Sarcomas appear to be met with more frequently in rats, and two or three different ones may be found in American laboratories. As far as known European laboratories have till now not possessed inoculable rat sarcomas, which fact bears out clearly the importance of the recent discovery of two of these tumors in Copenhagen. It is to be regretted, for the sake of the further study, that the mentioned tumors only exceptionally can be made to proliferate in rats of other breeds than the one reared in the Copenhagen laboratory.

Dr. O. V. Petersson of Upsala has carried out some researches on the possibility of infection arising from books used by patients affected with pulmonary tuberculosis. He examined case record forms which had been kept either hanging behind and above the bed's head, or lying on a little table near the patient, or, finally, on a table in the middle of the ward. The surface of the forms was washed with water, after the centrifugation of which tubercle bacilli were found in forty per cent. of the aggregate number of cases examined, while he failed to discover bacilli in those cases in which the record forms had been kept in the middle of the ward. In the opinion of the investigator this fact goes to show that Flügge's drop infection was to be held responsible for the contamination of the forms, also because the bacilli were often seen to be in groups round clusters of leucocytes. His surmise was corroborated by the following experiments: He made consumptive patients when coughing hold up a sheet of paper in a distance of thirty cm. from their mouth and was always able to demonstrate the presence of tubercle bacilli in the dust which he could scrape off the paper. The natural deduction of these researches is that books handled by consumptives ought to be regarded as a possible source of infection and to be treated accordingly. The fact that Dr. Petersson found bacilli on forms, which had been kept for several years shows that books may remain dangerous for a long time.

The Statistical Bureau of the State of Denmark has published a report on suicides and accidental deaths in the years 1896-1905. The number of suicides was 22.1 per 100,000, the incidence for men being four times greater than that for women. Suicide caused by addiction to drink is twice as frequent in Copenhagen as in the country. Of the male suicides between 25 and 65 years of age every second was a drunkard. More than 600 deaths by accident are registered yearly, 150 of which happen during work while only 60 are covered by the workmen's liability act. Of the aggregate number of males above 15 years of age having perished by accident, one-fifth were addicted to drink. The statistics for men between 45 and 65 years present a still darker aspect, one-third of the perished being drunkards.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 24, 1907.

Treatment of Stricture of the Urethra.—Twenty-five years of experience in the treatment of urethral stricture have led F. R. Watson to the following conclusions: (1) Electrolysis and divulsion are methods of treatment which should both be abandoned. (2) Internal urethrotomy is the only method of treatment by which an important number of cures can be obtained. It is an operation involving but little danger. Its application should be restricted to strictures within the first five inches of the canal unless external perineal urethrotomy is done in combination with it. (3) For strictures of the deeper part of the canal gradual dilatation is the best form of treatment if constitutional disturbance does not rise in connection with its employment, and if the urethra for a reasonable length of time maintains the caliber to which it has been expanded by the instruments. (4) For the cases in which the strictures of the deep urethra recontract rapidly after dilatation, or those in which constitutional disturbances arise in the course of its employment, also for the resistant or impassable strictures of the deep urethra, in all of which conditions gradual dilatation is useless, external perineal urethrotomy, or internal urethrotomy combined with the external incision in the perineum is the safest and most efficient method of treatment. (5) External perineal urethrotomy is the only operation that should be applied in cases of stricture accompanied by urinary extravasation. (6) Resection of the strictured part of the canal should be selected in cases of intractable, very dense strictures of the perineal part of the canal. Internal urethrotomy done under the conditions and in accordance with the rules the author has stated above will yield from 50 per cent. to 60 per cent. of radical cures, and at an operative risk of death of about 1.5 per cent.

New York Medical Journal, October 26, 1907.

Late Secondary Hemorrhages Following the Removal of Adenoids.—F. L. Wachenheim saw two cases in consultation, one a girl of nine years with bleeding on the fifth day, and another, a girl of the same age, with bleeding after five days. The local application of strong vinegar seemed to act as the best hemostatic. In neither case was the operation done under general anesthesia. Forceps were used in one case and the curette in the other. Neither child was a bleeder. Such cases of bleeding are probably due to incomplete removal of the lymphoid tissue or to septic infection and sequestration of a clot. The author thinks that hemorrhage more often follows the forceps than it does the curette. The latter is more likely to leave a clean section. Adrenalin seems to be ineffective in these cases. At best its results are but temporary. Vinegar applied through the anterior nares answers well. Plugging should be avoided as long as possible. The author's three suggestions are: First, operation with the curette under general anesthesia; second, caution to the parents as to the possibility of hemorrhage, together with full directions as to diet and management of the child for a week after operation.

Diseases of the Eye, Ear, and Throat Among Persons Affected with Leprosy.—In the material coming under the observation of H. T. Hollman in the Sandwich Islands were 60 eye cases, 25 ear cases, 100 nose, and 100 throat cases. Of eye diseases he found ptosis (4), ectropin or entropion of the lids (55), edema of the lids, tubercles, symblepharon, leprous ophthalmia, ophthalmia neonatorum, a leprous pterygium like pannus, corneal ulcerative iritis, leprous tubercles in the choroid, and retinitis. Ear diseases among lepers present nothing peculiar except the tuberculous formations involving the meatus, and in the leper most diseases can be traced to causes originated by the leprosy bacillus. In the nose there is a septal perfo-

ration in 75 per cent. of the cases and sometimes the septum is entirely gone. Hypertrophic cases bleed more freely than ordinarily. In two cases the turbinal tissue prolapsed on the floor of the meatus. Abscesses were found in the middle of the mass and were cured by injection of caustics. Atrophic rhinitis presents the usual appearance of the disease. Leprous tubercles are frequently found in the nasal cavity. A few cases of antral disease were found, probably from decayed teeth. A peculiar deposit of white leper tubercles often affects the tonsils. These swell and later become fibrous. They decrease in size under silver nitrate solutions. The pharynx is generally hyperesthetic and may present the usual tubercles. The larynx is frequently invaded by extension and may become so occluded as to call for trachotomy.

Hematuria of Renal Origin.—A general description of this malady is given by Hm. Christian, who believes that the hemorrhage of essential hematuria and of a certain proportion of cases of chronic interstitial nephritis are so intimately associated that it is a difficult problem to separate one from the other. The diagnosis as to the source of blood, whether it comes from the bladder or kidney where the bolod is passed intimately mingled with the urine, is often a most difficult proposition. In most cases, however, a careful study of the clinical symptoms present, together with the information gained from an examination of the urine and from the use of the cystoscope or some form of urine separator, will enable one to arrive at a fairly accurate idea as to the source of the hematuria. As regards the clinical features, those having the most bearing upon determining the source of the blood, are pain and frequent urination. All things being equal, hematuria associated with pain over the lumbar region with or without frequent urination, is of renal origin. On the other hand, where there is marked pain over the bladder, together with decided increased frequency of urination, one is justified in regarding the bladder as the probable source of the hemorrhage. The character of the bleeding and the macroscopic appearance of the urine are important factors in determining whether the bladder or kidney is involved. Hemorrhage from the bladder is apt to be intermittent in character, suddenly appearing and as suddenly disappearing. The urine is blood red in color, and is apt to be alkaline in reaction; on the other hand, hemorrhage from the kidney imparts to the urine the well known "smoke color" appearance, the urine is generally acid and contains from time to time small wormlike clots of blood which are known to be casts from the ureters. If, as Ayres has noted on bladder irrigation, the blood rapidly disappears and quickly reappears, it probably comes from the kidney; if it disappears slowly and returns slowly, probably from the bladder. The cystoscope is an aid to diagnosis, but the ureteral catheter and the urine separators are not of much value. The author thinks that there is no question as to the propriety of a nephrotomy in those cases in which the bleeding is profuse, continuous, and threatens life.

Journal of the American Medical Association, November 2, 1907.

Lymphosarcoma in Dogs.—The results of recent observations on a particular type of tumor occurring naturally in dogs and known under the name of "infectious lymphosarcoma" are reported by S. P. Beebe. It has been considered by some pathologists, notably Bashford, to be an infectious granuloma, comparable in many respects to syphilis. Beebe's observations, however, are directly opposed to this; he finds no evidence of its transfer except through transplantation of a living tumor cell, and hence cannot consider it infectious in the sense of having a microorganism as its cause. Microscopic studies have revealed no germs, except in one case in which the organisms were those occasionally found in ulcerating areas, and were in no way similar to those found in mouse carcinoma. As observed at the Buffalo Laboratory in the studies on mouse carcinoma, so here a certain percentage of the tumor animals recover spontaneously and acquire an immunity, though not an absolute one. A tumor already growing does not, however, confer immunity to secondary implantations. Beebe is inclined to believe, from transfusion experiments made with the cooperation of Dr. Crile, that the blood contains immune factors that confer a passive immunity to susceptible animals. The detailed report of these experiments is promised later. So far as the facts of Beebe's observations can be applied to the human subject, they indicate that there is no reason to consider human tumors infectious to any greater extent than those here studied in the dog. It is possible that they can be transplanted, but we cannot argue from this that certain houses or water courses are sources of infection. His efforts to find a cure have been limited to his study of the mixed toxins advocated by Dr. Coley for the treatment of sarcoma. The results have been interesting and demonstrate the value of the method. It also shows the instability of the tumor cells as compared with normal cells, since a great variety of toxins affect them unfavorably. Their growth function seems excessively developed, but their defense is weak.

Experimental Epithelial Proliferation.—Incited by Fischer's results with Scharlach R. and olive oil in producing epithelial proliferation in the rabbit's ear, G. McConnell undertook further experiments along the same line on Belgian hares, guinea pigs, and white rats, using a mixture of Sudan III with olive oil. Practically similar findings with those of Fischer were obtained—proliferation of epithelial cells with prolongations downward, increase of connective tissue, etc. He considers the results suggestive as regards the origination of malignant growths, though they do not reach a point where definite conclusions can be drawn. If we can bring about such an atypical proliferation of the epithelium it would seem theoretically possible to continue the stimulus to the point of having a destructive growth. Hints of this appeared in the form of a slight ulceration that was observed in one experiment, but, with the exception of Fischer's case in which there was apparently an infiltration of the ear cartilage, no such result has been obtained.

Osteoplastic Operations.—Prof. D. Küster gives a résumé of the history and present status of osteoplastic surgery, pointing out the variations of which it is capable and calling attention to certain facts in his own experience. He briefly describes his method of "osteoplastic exarticulation in the foot-joint," his method of performing cranial osteoplasty and his use of the osteoplastic method to avoid deformity after mastoid, antral, and sinus operations. He also gives briefly his experience with other osteoplastic operations, and points out that osteoplastic methods in general, and the transplantation of pedunculated flaps in particular, have given very satisfactory results. These, as enumerated by him, are: A better survey and accessibility of the field of operation, avoidance of grave and persistent interference with health, and, finally, avoidance or diminution of deformities.

Prolapse of the Ovary.—G. G. Ward, Jr., considers that the prolapse of the ovary is of greater clinical importance than some authorities at present seem to allow. While it may exist without symptoms in some cases in which the organ is probably free from inflammation or adhesions and has ample room for movement, in many others it gives rise to characteristic painful symptoms which can only be relieved by operative interference. Failure to recognize the ovarian prolapse accompanying retrodisplacement of the uterus is often the cause of lack of success in the operation for the relief of the latter condition. He rejects any operations by shortening or folding the ligaments to elevate the ovary, and holds that the Mauclaire-Barrows operation of transplanting the ovary to the anterior surface of the broad ligament through an incision or buttonhole offers complete relief and makes recurrence impossible, is very simple and easy of execution and does not interfere with the functions of menstruation or fecundation. He reports eleven cases thus treated successfully by him. The operation can be combined with suspension of the uterus, Gilliam's operation, shortening the round ligaments, or the infundibulopelvic ligaments for an accompanying retroversion or uterine prolapse, and can be performed by the vaginal route much more easily than the other operation. The operation is described and illustrated.

Erysipelas.—L. N. Boston and A. E. Blackburn find the incidence and mortality of erysipelas are both decidedly affected by seasonal influences, being highest in the colder months. Age also is an important factor in the mortality, the latter being excessive in early infancy, least in childhood, and gradually increasing from adolescence to old age, when it again becomes excessive. Among their cases both incidence and fatality were very markedly greater in the male than in the female. Their statistics also show that renal complications are to be expected with erysipelas, since of the 483 patients examined in this regard, 327 (67.7 per cent.) were voiding pathological urine. The mortality, however, did not apparently indicate that it was a very serious complication. In 66 of the cases the disease was limited in extent, in 486 it was extensive. The scalp was primarily involved in 12 cases, but of the 485 cases beginning in the face, in only 7 did the disease extend beyond the hair margin, the scalp remaining unaffected. The occurrence of glycosuria in a certain percentage of the cases is mentioned.

The Lancet, October 19, 1907.

Acute Intestinal Obstruction.—The patient of H. J. Clarke was a boy of 11 years with symptoms of three days duration, viz., violent abdominal pain, constipation, vomiting, pinched and drawn face, furred tongue, dark colored

but not distinctly fecal vomiting. Pain and tenderness were most marked over the left iliac region. Under light ether anesthesia on the third day a median incision was made from just below the navel to the pubes. The peritoneal cavity contained considerable clear fluid. Small intestine was congested and distended here and there. Cecum was flaccid. The tip of the appendix was found imbedded in the mesentery, forming a band under which the ileum was constricted. In the top of the appendix was a hard concretion. The appendix was ligatured and cut through, thus releasing the ileum. The patient's bad condition forbade a more elaborate procedure. The bowel was black in several places, but the intestinal wall retained its luster The abdomen was filled with saline solution and closed. A drain was left in for 24 hours and then removed. Recovery was uneventful.

Intraparietal Hernia with Very Small Peritoneal Opening, Giving Rise to Severe Abdominal Pain.—J. A. Macewan reports the case of a woman of 57 years who had had for 27 years abdominal pain about midway between the navel and symphysis, about two inches to the right of the median line. A small umbilical hernia was found and later a mass the size of the closed fist with a narrow pedicle, extending toward the abdomen. On lying down, this mass disappeared with a sudden slip and a slight gurgle. The umbilical hernia was first treated and then the inner surface of the abdominal wall was inspected. At the point above named as painful, inspection revealed a small raised area with a minute central depression. So small was this depression that it was doubtful if it would admit a probe. Slight pressure with the point of the probe, however, served to gain access to what appeared to be a small sac in the abdominal wall. Dressing forceps were next tried and it was found that the minute mouth of the sac was extremely distensible, easily opening sufficiently to admit the finger, which penetrated a distance of one and a half inches when a little pressure was applied. An incision was now made round the mouth of the sac in the normal peritoneum and the sac, which then lay loosely in the abdominal wall, was dissected out. While very small when relaxed, and, as already stated, possessing a very narrow mouth, it was capable of great distention, extending easily to the size of a tangerine orange. A further point of interest was that the omentum, instead of lying in front of the coils of bowel, had become turned up, its free border being attached to the stomach and the whole being laden with fat. An attempt was made to remedy this and a redundant portion was removed. The wounds were now sutured, particular care being taken to secure accurate apposition of the cut peritoneal surfaces, and the patient was returned to bed. She made an uninterrupted recovery and has had no further trouble, the pain having quite disappeared.

Frontal Band Alopecia As a Possible Sign of Exophthalmic Goiter and Associated Conditions.—D. Walsh says that hairlessness in the band just above the forehead, if persistent into later life, constitutes the congenital frontal band alopecia. It is far more frequent in girls than in boys, and in later years is apt to be more or less hidden in both sexes by the hair being brought over the forehead, but more especially in women. The band may be quite bald; more commonly it has a few short hairs as it nears the hairy scalp. It is almost invariably associated with bays that run backwards in a line with the frontal eminences; the bays are usually covered with a thin growth of hair; the whole band may be thinly covered with hair, or one side only may be thus covered and the other bare, or there may be a thin pencil of hair on one or both sides, indicating where in normal circumstances the hairy scalp would have commenced. The band itself may be about half to one inch in width; it is situated at the anterior margin of the frontal portion of the scalp and stretches across from one frontal eminence to the other. It is not easy to lay down any exact line of normal limitation of scalp margin, but it may be regarded, as a rule, as extending to the upper half of the convexity of the frontal eminences. When the band is marked, or when it is indicated by a partial anterior rim of hair, there can be no doubt as to its presence. The congenital frontal band alopecia often runs in families and is hereditary. In one case an acquired frontal band was added to a pre-existing congenital band. In both children and adults the author has found it constantly associated with enlargement of the thyroid and tachycardia, nervousness, pigmentation, chilblains, epistaxis, patchy baldness, and sometimes tremors, a condition that suggests potential Graves' disease. In 18 cases of exophthalmic goiter the congenital frontal band alopecia has been found present, and no negative instance has so far occurred. Out of six cases of myxedema the frontal band alopecia was found in five, of whom two showed unequivocal and the other three less marked signs and symptoms of exophthalmic goiter. The sixth had no frontal band alopecia and nothing to suggest past or present Graves' disease. So far some 96 cases of frontal band alopecia have been investigated. The band may possibly indicate some evolutionary change or may be degenerative or trophoneurotic, or be a part of the obscure group of signs and symptoms associated with exophthalmic goiter.

Blood Pressure in Fevers.—A study of this subject has been made by J. Davidson. In scarlatina he found that the blood pressure curve very similar to those of the pulse and temperature. In general it continued to fall until the seventh or eighth day of the disease, at which time it usually passed below the normal line. In about 5 per cent. of the cases it remained normal throughout the entire disease. In the severe cases of scarlatina of the anginose type, the pressure fell as the toxemia increased, in spite of cardiac stimulation. In scarlatinal nephritis the blood pressure is raised during the period of albuminuria. The rise often occurs before the albumin appears. In diphtheria a reduction in pressure was found in every case depending largely if not entirely on the degree of toxemia. Mild cases showed normal or slightly subnormal readings. In antitoxin injections a rise appeared in temperature four or five hours after injection, but the vascular pressure was found in almost every case to be either reduced or the same. In general this reduction appeared in a few minutes and passed off within an hour. In typhoid the blood pressure is always considerably lowered, the diminution progressing steadily the longer the continuation of the case, and it rises again only on the establishment of convalescence or the occurrence of some acute inflammatory complication. In all such operations it is evident that we must carefully distinguish the changes attributable to the fever itself from those which are merely secondary to the pyrexia.

British Medical Journal, October 19, 1907.

The Calmette Serum Reaction in Ophthalmology.—S. Stephenson gives a brief review of the Calmette test and has applied it in some thirty or more cases, all of whom were suffering from some eye affection. His results may be summarized as follows: (1) Phlyctenular (eczematous conjunctivitis and keratitis), 6 cases, with corneal ulceration reaction in all positive; 1 case of recent phlyctenular keratitis; reaction negative. (2) Choroiditis, 3 cases, reaction positive in all. (3) Interstitial keratitis, 8 cases; 5 with stigmata of inherited syphilis, all negative, in the remaining 3, all positive. (4) Episcleritis, 3 cases, 1 positive and 2 negative. (5) Tubercle of the iris, 1 case, positive. (6) Tubercle of cornea, 1 case, positive. (7) Chronic iridocyclitis, 1 case positive. Stephenson adds that according to Calmette, neither ordinary tuberculin nor Koch's older tuberculin (*Alttuberculin*) must be employed in the test, since their contained glycerine is apt to irritate the conjunctiva and thus to mask any proner reaction. Calmette advises 1 part of dried tuberculin, precipitated by alcohol, dissolved in 100 parts of sterilized water, and of this liquid he places one or two drops in the eye to be tested. The Pasteur Institute, Lille, France, prepares suitable tuberculin in two forms: (1) as dry tuberculin in small glass phials, to which the surgeon adds ten drops of water; and (2) as a solution in hermetically sealed glass tubes, each of which contains several drops of the product ready for immediate use. The price of neither preparation is prohibitive.

Two Cases of Pernicious Anemia with Unusual Features.—These case histories are given by J. Fortune. Case 1 was that of an epileptic man of 30 years, who died after six months of symptoms. Autopsy showed an empty gall-bladder, contrary to the rule. The anemia served to lessen the number of epileptic seizures, though in what manner it is difficult to determine. Case 2 was that of an imbecile woman of 25 years who had a long illness of nearly two years, beginning with the deposit of patches of brown skin over the front of the chest and abdomen. Some two years later she presented a very peculiar appearance. Her hair and face were very white and the mucous membranes pale. The anterior aspect of the trunk was of a bronze color, with the exception of several small patches with well-defined outlines, which were of the same aspect as the face. It was difficult at first to decide which areas represented pigmentary anomalies. Towards the axillæ and genitals the color was deeper, and over the thighs small spots the size of a lentil were distributed, gradually becoming rarer as the knees were reached. The back of the trunk and thighs, the arms, and the legs below the knees, were pale and not pigmented; nowhere could a lemon tint be discovered. A blood count gave the red corpuscles as 1,100,000 per c.mm. There was marked poikilocytosis, and alteration in size, and many nucleated red corpuscles. Hemic murmurs were present, and some tenderness over the long bones. There was never any edema or hemorrhages and the temperature varied between 99° and 100° F. The patient had complained mostly of feeling cold.

Autopsies were made in both instances, and the ferrocyanide test applied and bone marrow examined. No extravasations could be determined in either with the naked eye. In both the fat was of bright yellow color, and the internal organs pallid. Gigantoblasts were found in the bone marrow. Further pathological changes in the various organs were those characteristic of the disease in general.

Berliner klinische Wochenschrift, October 7 and 14, 1907.

Paratyphoid Fever and Food Infections.—Kutscher discusses the relationship between paratyphoid epidemics and the use of infected meat. Clinically, etiologically, and pathologically there is entire correspondence between the ordinary paratyphoid fever and certain instances of meat poisoning, and therefore these must be regarded as paratyphoid fever with a special mode of infection. From a study of a number of epidemics of this sort it appears that in almost all the cases meat was used from animals slaughtered because they were sick. Prophylaxis, therefore, demands that no meat from animals suspected of disease shall be used for human consumption until its harmlessness has been demonstrated. This means that bacteriological investigation is necessary in each case, for the meat from animals suffering from septic or pyemic disorders is often free from all visible signs of disease shortly after slaughtering. The use of raw meat is to be discouraged, and Uhlenhuth's suggestion that the temperature of all animals be taken before slaughtering and those having fever be regarded as suspicious is a good one.

Infected Hydronephrosis with Anomalous Ureter.—Manasse describes a case of hydronephrosis occurring in a man of twenty-six years, which was recognized as such owing to the fact that after a diagnostic inflation of the stomach and rectum the urine, which previously had been clear, suddenly became purulent and the tumor decreased in size. At the operation it was found that the renal parenchyma was almost entirely destroyed, while the larger part of the cyst was formed by the greatly dilated renal pelvis. The ureter was patent, and instead of passing over the posterior surface of the organ ran downward over its anterior surface. The vessels entered the hilus behind the ureter. The kidney had been very little displaced, but the spleen lay in the midline of the body in front of the vertebral column close to the stomach. The cyst contained 3,500 c.c. of purulent fluid. The patient made a good recovery.

Opening Peritonsillar Abscesses.—Meyer advises opening such abscesses through the supratonsillar fossa. It is at this point, he says, that the infection usually begins and from this direction the abscess cavity is most easily to be reached. The method has the advantage that a blunt instrument may be used while it is easily possible to discover collections of pus so small as to be reached only with difficulty by means of the ordinary incision. He uses for the purpose a blunt hook whose bent part is a little over a centimeter in length. The patient's tongue is depressed and the point of the hook is introduced into the fossa. It follows the line of least resistance, usually upward and outward, and then the opening is widened by a sharp pull. If the abscess is very deep or behind the posterior pillar it may be necessary to penetrate through the posterior pillar itself, or between this and the tonsil, or through the latter. Incision through the anterior pillar is practised only in very advanced cases that are almost ready to burst. The author greatly prefers the use of the hook in this way to incision, especially as it often enables very early evacuation of the abscess and therefore tends to shorten the duration of the illness.

The Preservation of Complements.—Friedberger, in experimenting with complements, found that the addition of 4 per cent. of sodium chloride was very effective in preventing the deterioration of the activity of the serum at room temperature. The addition of the salt did not render the serum more resistant to the action of high temperatures, however. The author does not believe that the effect of the salt is due to a bactericidal action and considers that the salt either causes the complement to assume a more stable form, or destructive substances present in ordinary serum are restricted in their activity. Preservation of the complement is also effected by drying the serum at room temperature. Such complement also is rendered much more refractory to high temperatures. Whereas the complement is destroyed by heating to 56° for half an hour in fluid serum, after drying it stands heating for an hour and a half at 64° with a loss of only about one-half of its former value.

Münchener medizinische Wochenschrift, October 8 and 15, 1907.

The Morphology of Urine and Bile.—Veit and Wederhake say that Virchow first described small bodies giving a reaction similar to starch with certain reagents and therefore called corpora amylacea. These are found in the substance of the spinal cord in the ependyma of the cerebral ventricles, in the prostate gland and its secretion, in the lung, in the sputum in pulmonary tuberculosis and bronchial asthma, in carcinoma, in the colostrum, in the urine, and bile. Several methods for staining these have already been described, but the authors prefer the following procedure: The fluid in question is centrifuged and the supernatant fluid is poured off. To the sediment a drop of tincture of iodine is added and the tube is well shaken. Then 1 c.c. of concentrated solution of croceinscharlach 7 b in 70 per cent. alcohol is added and the whole is well shaken. The sediment is then washed by recentrifuging with water and may then be examined or preserved in Farrant's medium. The typical amyloid bodies are stained bluish black or a lighter blue, but in addition to these other similar bodies are also found which are stained red and exhibit slight morphological differences. The authors believe that the discovery of these true amyloid bodies in the urine has diagnostic value in distinguishing between bladder and renal affections. The absence of amyloid bodies from a pathological urine indicates that no catarrhal bladder affection exists, whereas there their presence shows that this organ is also involved. The authors do not offer any suggestions as to the origin of these bodies, but as they occur in scrapings of the interiors of gallstones they consider it possible that they have something to do with the formation of vesical calculi as well as of gallstones.

Treatment of Iritis and Ophthalmia Neonatorum.—Fukala says that in treating iritis and iridocyclitis two conditions must be fulfilled: first, the pupil must be dilated to the maximum, and second, a specific remedy must be used for the cure of the inflamed iris and ciliary body. In order to carry out the first condition it is necessary to use stronger solutions of atropine than is usually done, and two, three, and even four per cent. solutions must at times be resorted to. The author has never seen any disadvantages attending this practice, but as soon as the pupil reaches the stage of full dilatation he omits the atropine until contraction begins again. In addition, as a specific remedy, a 1-4,000 solution of corrosive sublimate is applied by means of a pledget of cotton held in a forceps. The application must be preceded by cocainization with five, ten, or fifteen per cent. solutions of the anesthetic, and the bichloride is brought into contact with the whole of the scleral conjunctiva. It is advisable to warm the solution to 36° C. In grave cases a compress soaked in 1-4,000 bichloride solution is applied over the entire eye and if the pain is severe leeches are used. For ophthalmia neonatorum Fukala recommends the use of stronger solutions of silver nitrate than are ordinarily employed, and he states that although the two per cent. solution may serve in mild cases, for the more serious ones a strength of four and even five per cent. is necessary. This solution also is applied with a pledget of cotton, and in adults preliminary cocainization is advisable in order to render the application less painful. In the specific ophthalmia of adults the remedy is abortive if applied sufficiently early, but later on in the disease its effect is less satisfactory.

Pain and Blood Pressure.—Curschmann investigated the question of the behavior of the blood pressure in the presence of painful stimuli. For this purpose he subjected various groups of individuals to painful electrical stimuli, recording the blood pressure before and after. One set comprised persons with normal sensibility; these reacted with an elevation of 8 to 10 mm. of Hg., though in two out of twenty a drop of 10 to 15 mm. was caused. In persons with neurotic or organic hypertension the elevation produced was still greater, and the author considers that it may be accepted that both in well and sick persons with normal skin sensitiveness the application of painful stimuli causes a rise in blood pressure, more rarely a fall. In disturbances of sensibility either through organic disease or hysteria, this result did not follow. In gastric and intestinal crises in tabes the blood pressure was found to be very high as well as in lead colic, whereas in instances of abdominal pain due to other causes, such as carcinoma of the stomach, gallstones, etc., this was not the case, and he suggests that this sign may have diagnostic value.

Fatal Reflex Anuria Following Urethral Examination.—Bennecke describes this case in which death occurred under circumstances that in private practice might have been very embarrassing. The patient was a man of sixty-five years who first came under hospital treatment for

chronic nephritis and cystitis. For a time he was in a condition of chronic uremia, but gradually recovered from this and after some weeks of convalescence was subjected to the exploration of the urethra with sounds, as the presence of strictures was suspected. None were found but some difficulty was encountered owing to spasm at the vesical sphincter and the patient complained of severe pain. This increased, he became delirious and then comatose, dying thirty hours after the examination. During this time not a drop of urine was voided and at the autopsy none was found in the bladder. The author says that the condition is difficult to explain, but that it apparently was due to reflex inhibition originating in the spasmodically contracted sphincter of the bladder. The autopsy showed that there had been no injury to the urethra by the instrumentation.

Deutsche medizinische Wochenschrift, October 17, 1907.

Experiences with the Quartz Lamp.—Heymann reports on the results obtained in the treatment of various skin diseases by means of the quartz lamp as opposed to the Finsen lamp and various modifications of this. He comes to the conclusion that the quartz lamp possesses the decided advantages of being more convenient to manipulate, less expensive, and requiring smaller amounts of current, but that it has the advantage of easily causing deep necroses that are slow to heal. By exposing the forearm under a rabbit's ear to the rays of both lamps it was found that the quartz lamp possessed much greater penetrating power than the Finsen lamp. The author regards it as a useful adjunct to the treatment of lupus, of value in eczema through its sedative and siccative effect, and of service in superficial nevi without tissue hypertrophy. It also gives good results in the treatment of all forms of acne.

The Occurrence of Mydriatic Substances in the Urine.—Pal says that the observation of Schur and Wiesel that the serum of nephritics contains mydriatic substances induced him to carry out similar experiments with the urine of patients suffering from various affections. The test was carried out on the enucleated eye of the frog. Eighty-one cases were tested in all; the reaction was not present in any of the seven normal cases; it was present in 78 per cent. of twenty-eight cases of nephritis, in 7 per cent. of twenty-eight cases of various other diseases, and in 33 per cent. of eighteen cases of pregnancy. The question is to be investigated further and the author suggests that the mydriatic action may be due to the excretion of adrenalin.

French and Italian Journals.

Retroperitoneal Tumors.—Mangiagalli presents the histories of five retroperitoneal tumors of large size removed with excellent results. These tumors have their origin in aberrant embryonic remains of the genitourinary organs. In operation the incision should begin at the superior pole of the tumor and extend down into the peritoneal sac, thus facilitating the removal of the tumor. The cervix uteri is little increased in size and is no obstacle to the ligation of the utero-ovarian artery. The cavity left by the removal of the tumor may be treated in various ways. It seems best to tampon the cavity with sterile gauze after having separated the retroperitoneal from the peritoneal cavity. The cavity generally contracts rapidly.—*La Riforma Medica*, September 15, 1907.

Intramuscular Injections of Drugs.—Bartolomeo Rossi reports cases treated by intramuscular injections of various drugs. Biniodide of mercury is less painful when used as injection material than the bichloride, because the solutions are perfect and the injections are easily made in the retrotrochanteric and gluteal regions. They should be made slowly and followed by massage. The use of iodomercurial preparations for injections is absolutely painless, of rapid action, efficacious even when the injection of other preparations is not tolerated, avoids the toxic action of the iodide upon the stomach, and is most effectual in late syphilis and in cases complicated with tuberculosis. *Giornale Internazionale delle Scienze Mediche*, September 15, 1907.

Therapeutics of Dystocia from Pelvic Deformities.—A. Pinard gives the statistics of one hundred cases in which he interrupted pregnancy for pelvic contractions, the results being recovery in ninety-nine cases and death in one. There were eighty-three living infants, seventeen that died during labor, sixteen dead before they left the hospital, and sixty-seven that remained well and strong. In pregnancy we have a chance of premature birth, while in labor we have the danger of wounding the mother. The less operations we practise the better. The author has abandoned premature labor whenever symphyseotomy will allow of delivery. Forceps should never be used where there is bony resistance. In such cases enlargement of the pelvis is indicated. In cases of absolute contraction utero-ovarian amputation is in order. Embryotomy in the living infant should be discarded. During labor two dangers are to be avoided; length of labor and infection. The conservative cesarean section may be indicated, accompanied or not, by partial or total hysterectomy. Embryotomy should be made use of only in case the fetus is known to be dead.—*Annals de Gynécologie et d'Obstetrique*, September, 1907.

Otic Sclerosis and Its Relation to Arteriosclerosis.—Souleyère distinguishes two forms of otosclerosis, one frequent in young persons and of the adhesive type, resulting from suppurations and catarrhs of the ear; the other a true sclerosis, occurring only in later life, especially after thirty years of age. This he calls pure otosclerosis. Heredity has importance as a factor in its production. So have chronic diseases such as syphilis. Its early symptoms are negative, deafness that is progressive, tinnitus, and dizziness on the principal ones. It is relieved by removal of cerebrospinal fluid. There is present hypertension in the arterial circulation, and treatment for its relief is of value in helping this form of otosclerosis.—*La Presse Médicale*, July 27, 1907.

Trephining Early in Fractures of the Skull.—L. Latour advocates early trephining in fractures of the skull that are or are not accompanied by cerebral symptoms. In some cases at first there are no bad symptoms, and after a short period of improvement suddenly severe symptoms manifest themselves that are due to abscess in the brain, and surgical interference is now too late. Besides these considerations we must consider the cases of Jacksonian epilepsy that occur as a result of fracture of the skull. Early trephining would enable the removal of pressing portions of bone that cause epilepsy later on. Hernia of the brain through the opening left by the trephine is generally inflammatory, being sometimes the result of superficial, sometimes of deep suppuration. The author operates with much caution in an exploratory manner to prevent infection of the brain substance.—*La Presse Médicale*, August 14, 1907.

Wine and Typhoid Fever.—P. Carles discusses the question whether the use of wines to modify water that is suspected of impurity will be any safeguard against typhoid fever. He has made experiments with various forms of French wines as to their effect on the typhoid fever germs, and finds that some of them have an appreciable bactericidal quality which is not dependent on the amount of alcohol that they contain, since it is not diminished by heating the wine and thus driving off the alcohol. White wines are more active than red ones, and especially champagne is valuable. The degree of acidity of the wine appears to be an important quality, since the use of an alkali destroys its bactericidal power. The amount of fluid with which the wine is mixed, as well as the time it is allowed to stand, both affect the bactericidal qualities of wine. Making the mixture some time beforehand and allowing it to stand before giving it to the patient has been found to be favorable to this power.—*Journal de Médecine de Bordeaux*, June 16, 1907.

Frequency of Tuberculosis in Infancy.—A. Lomini believes that tuberculosis in infancy is much more frequent than has been recognized. Autopsy shows this to be the case. These forms of tuberculosis may remain latent for years and only be revealed by autopsy. He collects and tabulates the cases on which autopsies were made at the Pediatric Hospital in Florence, from 1902 to the present time. From 437 autopsies on babies, 186 showed tuberculosis. The respiratory organs were found to be very frequently involved, while the intestines and abdominal organs were much less frequently affected.—*La Pediatria*, April, 1907.

Hematomyelia from Myelitis.—E. Medea describes an interesting case which showed the characteristic symptoms of acute myelitis while none of them suggested hematomyelia. The autopsy showed a softening of a portion of the medulla commencing at the last dorsal segment. At and above this point was a hemorrhagic focus occupying the left lateral portion of the medulla over several segments of the spinal cord. There were many lymphocytes, and an accumulation of pigment cells and true macrophagi in phagocytic function. There was severe infiltration of the meninges at another distant point. There were also circumscribed necrotic foci characteristic of myelitis. The onset was sudden, with fever and no symptoms of hematomyelia. It is thus seen that a focus of hemorrhage in the spinal cord may remain undiagnosticated during life if accompanied by dominant symptoms of myelitis.—*La Riforma Medica*, July 27, 1907.

Book Reviews.

Handbuch der Pathologie des Stoffwechsels. Unter Mitwirkung von Adalbert Czerny, Carl Dapper, Fr. Kraus, Otto Loewi, Adolf Magnus-Levy, M. Matthes, Leo Mohr, Carl Neuberg, Hugo Salomon, Ad. Schmidt, Franz Steinitz, H. Strauss, W. Weintraud, herausgegeben von Carl von Noorden, Wien. Zweite Auflage. Zweiter Band. Berlin: August Hirschwald, 1907.

The second volume of von Noorden's monumental work on metabolism opens with three essays by v. Noorden on diabetes mellitus, gout, and obesity, respectively. Then follow others in the rarer anomalies of carbohydrate and proteid metabolism, skin diseases, ductless glands, cancer, metabolism in childhood, oxaluria, and phosphaturia, mineral waters, and baths, phototherapy, drugs and poisons, nervous and mental diseases, diseases of bones and joints, and diabetes insipidus. These are by the various collaborators though the name of the editor appears as coauthor of several. The completed work as it now stands is more than double the size of the first edition and is an excellent example of the admirable type of reference works produced in such numbers in Germany and so rarely elsewhere. It will, no doubt, stand as an authority for many years to come.

Diseases of Infancy and Childhood. Their Dietetic, Hygienic, and Medical Treatment. A Text-Book designed for Practitioners and Students in Medicine. By Louis Fischer, M.D., Visiting Physician to the Willard Parker and Riverside Hospitals of New York City; former Instructor in Diseases of Children at the New York Post-Graduate Medical School and Hospital, etc., etc.: Fellow of the New York Academy of Medicine. With 303 text illustrations, several in colors, and twenty-seven full-page half-tone and color plates. Philadelphia: F. A. Davis Company, 1907.

The current year has been rather prolific in new treatises on various branches of medicine—surgery, dermatology, practice, etc.—and now comes a new work on pediatrics. The work is divided into twelve parts: I., The Newborn Infant; II., Anomalies and Diseases of the Newborn; III., Feeding in Health and Disease; IV., Disorders Associated with Improper Nutrition, and Diseases of the Mouth, Esophagus, Stomach, Intestines, and Rectum; V., Diseases of the Heart, Liver, Spleen, Pancreas, Peritoneum, and Genitourinary Tract; VI., Diseases of the Respiratory System: VII., The Infectious Diseases; VIII., Diseases of the Blood, Lymph Glands or Nodes, and Ductless Glands; IX., Diseases of the Nervous System; X., Diseases of the Ear, Eye, Skin, and Abnormal Growths; XI., Diseases of the Spine and Joints; XII., Miscellaneous. The author has had not only an extensive clinical experience, but also a wide teaching experience, which has admirably fitted him for the difficult task of writing a new text-book on an old subject. Pathology and bacteriology are considered at all-sufficient length, but special attention is paid to the more practical subjects of symptoms and treatment. The work is freely but judiciously illustrated with a number of colored and half-tone plates and over three hundred pictures in the text. If the outside of the book were as good as the inside it could be warmly commended. Unfortunately the publishers have emblazoned on the back an offensive legend asserting that this is "the best"—they ought to say "the limit;" whatever best it is, it certainly is the worst taste.

Practical Physiological Chemistry. A Book Designed for Use in Courses in Practical Physiological Chemistry in Schools of Medicine and Science. By Philip B. Hawk, M.S., Ph.D., Demonstrator of Physiological Chemistry in the Department of Medicine of the University of Pennsylvania. With Two Full Page Plates of Absorption Spectra in Colors, Four Additional Full Page Color Plates, and One Hundred and Twenty-six Figures, of which Twelve are in Colors. Philadelphia: P. Blakiston's Son & Co., 1907.

While written more from the laboratory than the clinical standpoint, the present volume is in every way to be commended for the use of students and practitioners By the adoption of a concise mode of presentation and excellent typographical arrangement the author has kept the size of the work within reasonable limits and has greatly facilitated its perusal. The order in which the various topics are taken up is good and the plan of leaving the discussion of the urine, perhaps the most important section from the medical student's point of view, to the last scene appropriate. In several respects the text is more complete than in most of the smaller works on the subject. This is particularly the case in regard to decomposition of proteids and the chemistry of the solid tissues such as muscle and bone. An original and valuable feature is the presentation of schematic tables for use in analytical work. The illustrations are numerous and for the most part of good execution, a few, for example the one purporting to portray normal erothrocytes and leucocytes, being susceptible of improvement, however.

Morris's Human Anatomy. A Complete Systematic Treatise by English and American Writers. Edited by Henry Morris, M.A. and M.B. (Lond.), F.R.C.S. (Eng.), President of the Royal College of Surgeons of England, Consulting Surgeon to Middlesex Hospital, London; Honorary Member of the Medical Society of the County of New York; Formerly Chairman of the Court of Examiners of the Royal College of Surgeons; Examiner in Anatomy in the University of Durham, and Examiner in Surgery in the University of London, and J. Playfair McMurrich, A.M., Ph.D., Professor of Anatomy, University of Michigan; Member Association of American Anatomists; Member of Advisory Board, Wistar Institute of Anatomy, etc. Frank Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son & Co., 1907.

In the new edition of this well-known treatise on anatomy a number of American writers have taken part in the revision of several sections, some of which indeed have been entirely rewritten by them. These writers are J. Playfair McMurrich of the University of Michigan, on Morphogenesis and on the Urinary and Generative Organs; Charles R. Barden of the University of Wisconsin, on Muscles; Florence R. Sabin of the Johns Hopkins University, on Heart, Blood-vessels, and Lymphatics; Irving Hardesty of the University of California, on the Nervous System; Abram T. Kerr of Cornell University, on the Ear, Nose, and Tongue, and on the Skin and Mammary Gland; C. Carl Huber of Washington University, St. Louis, on the Organs of Voice and Respiration, including the Mediastinum, and on the Ductless Glands. The American writers, indeed, now outnumber the British, although originally the treatise was entirely the work of British authors. There are over one thousand illustrations, a third of them printed in colors; most of these are fine examples of the illustrator's art. The volume is provided with a thumb index, facilitating ready reference to the various sections.

Manual of the Diseases of the Eye for Students and General Practitioners. By Charles H. May, M.D.; Chief of Clinic and Instructor in Ophthalmology, College of Physicians and Surgeons, Medical Department Columbia University, New York, 1890-1903; Ophthalmic Surgeon to the City Hospitals, Randall's Island, New York; Consulting Ophthalmologist to the French Hospital, to the Gouverneur Hospital, and to the Red Cross Hospital, New York; Adjunct Ophthalmic Surgeon to Mt. Sinai Hospital, New York, etc. Fifth Edition, Revised. With 362 original illustrations, including twenty-two plates, with sixty-two colored figures. New York: William Wood & Company, 1907.

The author of this work is to be congratulated upon the appearance of a fifth edition within seven years from its first publication. In addition to this there have been several reprints, and the book has been translated into five European languages, as well as being published in a British edition. The reasons for this popularity are not far to seek. The author started out with a concise, practical, and systematic manual intended for the student and general practitioner. The size of the book is small; rare conditions are merely mentioned; uncommon affections, of interest only to the specialist, are dismissed with a few lines; while the common diseases are described with comparative fulness. The book is unimpeachable in its accuracy; and has the further advantage of being well arranged, and simply and clearly written. The author has had the rare good sense to keep the succeeding editions on the lines originally laid out, with the satisfactory result that both students and general practitioners recognize this work as the one best adapted to their needs.

Practical Observations upon the Chemistry of Food and Dietetics. Second revised and enlarged edition. By J. B. S. King, M.D., Prof. Chemistry Hering Medical College, former Prof. Chemistry, Hahnemann Medical College, etc. Philadelphia: Boericke and Tafel, 1907.

As an introductory primer on dietetics for the use of the laity this book may possibly have some slight value. For the physician or even for the medical student it is entirely too brief and too elementary to serve any useful purpose. Furthermore, on the very first page we find it stated that carbon is a gaseous element: and also that none of the elements exist in the body in a free state. Fletcher's "discovery" is duly (or unduly) emphasized; and while Warren Hastings' views on the relation of food to bodily stature may possibly be of interest to admirers of that great man, they can hardly be said to possess any scientific value.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-third Annual Meeting, Held at Columbus, O., October 8, 9, and 10, 1907.

THE PRESIDENT, DR. HORACE H. GRANT OF LOUISVILLE, IN THE CHAIR.

THE scientific work was divided into medical and surgical sections.

SURGICAL SECTION.

Local Versus General Anesthesia in Rectal Surgery.—Dr. G. B. EVANS of Dayton, O., believed that by using a local anesthetic previous to general anesthesia the amount of the general anesthetic was appreciably lessened; the dread and fear were diminished, also shock and danger. Therefore, the combined method of narcosis, less anesthetic, suspending shock incident to conscious dread, as well as anesthetic shock, rendered more complete the operative area and consequently more satisfactory work. It was easy to operate on prolapsing piles, but not so simple to operate on piles above the sphincters, yet they demanded operative interference. Operation for hemorrhoids was serious, often attended by some shock, and the greatest caution should be observed to secure asepsis. He did not think it was best for patients that general practitioners should be taught that aseptic precautions at the time of operation and rest at home for a few days were unnecessary.

Dr. BERNARD ASMAN of Louisville gave a few reasons for some unsatisfactory results in the treatment of anorectal diseases. A correct diagnosis was always a first essential, for without it all treatment was largely guesswork. Of all rectal ailments, anal fissure was ordinarily thought to be one of the simplest and easiest to cure, yet experience frequently proved it to be most unyielding. Ninety-nine out of every one hundred of the laity assumed that all anorectal troubles were hemorrhoidal in character, and it was not uncommon for them to approach the physician with a diagnosis ready made, and to preface a description of the case in question with, "Doctor, I have piles." The doctor was then apt to accept the diagnosis with but a superficial examination, or perhaps no examination at all, and hence failure to afford relief followed. There were comparatively few cases of hemorrhoids pure and simple; they were usually complicated by other local disease, perhaps requiring attention at the same time if a perfect result was to be expected. Cases were cited in point.

Dr. B. MERRILL RICKETTS of Cincinnati said that surgical anesthesia should be eliminated as far as possible in all work, especially now as capital operations could be done under local anesthesia. Local anesthesia for the treatment of hemorrhoids should not be denounced, nor should local anesthesia be recommended for all kinds of hemorrhoids. There were certain hemorrhoids that could be removed radically without anesthesia. He cited such cases. The trend of the times was not to put patients to bed for days and weeks for the removal of hemorrhoids, when they could be removed at the office of the surgeon or at the homes of patients with impunity. Hemorrhoids should be properly classified, and each class should receive a separate and distinct treatment, some with and some without anesthesia; some with and some without ligature; some with crushing and some with simple incision.

Dr. J. RAWSON PENNINGTON of Chicago emphasized the importance of making a correct diagnosis. If a patient had a small contracted anus, with a few painful hemorrhoids, he or she should be given a general anesthetic and operated on. If the patient had a patulous anus, and the hemorrhoids were easily prolapsed, especially internal hemorrhoids, there was no need for a general anesthetic. He described his method of removing hemorrhoids. When the rectum was everted and the hemorrhoids were on the outside, with a pair of scissors they could be removed very readily, the rectum then dressed in extension, and putting into the bowel a rubber-covered tampon. When this was done there was no tissue under stress. Tissue under stress was not in the best possible condition to defend itself against infection.

Dr. H. O. WALKER of Detroit had operated on a large number of cases of hemorrhoids, and had not yet had serious bleeding from the rectum. Hemorrhoids should be operated on under the same surgical principles as were carried out in operating upon other parts of the body. If there should be hemorrhage, it could be controlled by ligature or hemostatic forceps.

Dr. E. B. SMITH of Detroit referred to the importance of making a complete and thorough examination. This could not be done under local anesthesia. He had never been able to do it, nor had he seen anyone else do it with satisfaction. He had had the privilege of operating secondarily on patients who had been operated on under local anesthesia. He operated on these cases under general anesthesia.

The Frequent Interdependence of Dislocated Kidney, Gall-Bladder Trouble, and Appendicitis.—Dr. EARL HARLAN of Cincinnati summarized the salient features of his paper as follows: (1) That dependent pathology, accompanying the primary lesion of dislocated kidney, gall-bladder trouble, and appendical irritation of a severe nature is of frequent concomitant occurrence. (2) Many patients have undergone operation for appendical trouble or gall-bladder trouble wherein the causal factor was a dislocated kidney, the latter producing pressure interference to the bile outflow or bowel current. (3) All patients presented for abdominal treatment, complaining of indefinite and recurrent distress, discomfort, and pain, the attacks being accompanied with the presence of an excess of stagnant gas at certain points in the bowel, and in which the involvement of the stomach, gall-bladder, and appendix are more or less equal, should receive the careful consideration of the physician, in order that an accurate differential diagnosis may be made. (4) In the vast majority of cases a freely movable kidney presents no pathology on the part of the organ itself, and this immunity may cover a considerable space of time, after which there may appear symptoms of functional and mechanical disturbance on the part of the stomach, cholecyst, and bowel. (5) On account of the wide and uncircumscribed range of pathological symptoms produced by a dislocated kidney, it is more often liable to go undiagnosed than are other symptoms producing abdominal lesions. (6) Permanent and complete relief results only from a correction of the primary lesion with its dependent pathology.

The Disposition of the Appendical Stump.—Dr. B. MERRILL RICKETTS of Cincinnati concluded that the stump should be as short as possible. Any one of the purse-string methods was dangerous. Ligation for the firm appendix and extirpation for the soft one were the better methods. Hemorrhage from the appendical vessels was a common accident and one that could be avoided. The escape of feces into the peritoneal cavity was also frequent. Infection from the stump occurred rarely. Adhesions resulting from a denuded stump, or mesocolon resulting from ligature, were of little consequence. Ligature around the stump without mucosa between it and a stenosed Gerlach valve would not cause pain, otherwise it might do so. A more definite classification of the pathological appendix and its results should be more generally accepted. The mortality in cases with vomiting, ileus, obstruction, peritonitis, and distention was much higher than reports would indicate. It was probably as great as 90 per cent., if not more. It was difficult to understand why so few such cases had been reported, and still more difficult to understand why there were absent in the work of one and numerous in that of others. The average per cent.

of mortality for acute cases (7.50) and the average per cent. for chronic cases (1.75) was probably a fair estimate for the work during the last five years. Linen and silk ligatures had more advantages than catgut, without the disadvantages, and should therefore be given preference. Ligatures of any material or character should be transfixed in any tissue, especially within the peritoneal cavity. Stumps of living tissue should be sutured or ligated with transfixion, especially if there were canals of any character within the stump.

Dr. H. O. WALKER believed in ligating the stump of the appendix. After tying off the appendix close to the cecum, he disinfected it with carbolic acid and alcohol, and then by means of a purse-string suture covered it up. As long as the suture material was aseptic, it did not make much difference what was used. He had never had a death from hemorrhage in appendicitis except where it occurred some ten days or two weeks after the operation, due to the sloughing of the omentum, rupture, and obstruction from a gangrenous condition of the arteries of the appendix from which the patient died.

Dr. A. M. HAYDEN of Evansville said that if one used silk or linen in uncomplicated cases there were liable to be suppurating sinuses as a result. In these cases he would use catgut, which, in infected cases, becomes disintegrated in seven or eight days, and there were no suppurating sinuses following. He used linen in all of his clean cases, but in the infected ones he preferred catgut.

Dr. CHARLES STOLTZ of South Bend, Ind., spoke of the use of the thermocautery, and believed if it was used it would afford hemostasis without the unsurgical method of tying off a mass and letting it stick up in the cavity, without knowing what would become of it.

Dr. CHARLES A. BONIFIELD of Cincinnati had excised the appendix, closed the wound with chromicized catgut, and then covered the surface by bringing the mesoappendix up over it. He had done this for several years, and to his knowledge had never had a patient die from the bowel opening.

Dr. RICKETTS, in closing the discussion, said the so-called absorbable ligatures failed in many of these cases, and that there was nothing better than catgut or linen. They could be boiled and thoroughly sterilized. He had done four hundred appendectomies, without a serious hemorrhage or infection, and had never had to take a ligature out. He never used catgut in his abdominal operations, but employed Pagenstecher linen for almost everything.

When Should Gastric Ulcer Be Treated Surgically?—Dr. MILTON R. BARKER of Chicago said that all cases of gastric ulcer, regardless of any class in which they might be placed, excepting the neglected class, should primarily be treated medically, but that in the light of surgical achievements in this malady the internist had a double responsibility to his patients: First, to do all his methods could do, and, second, to discontinue those methods before his patient had reached such a condition that surgical methods could not be instituted without undue hazard. When medical and surgical science could thus work together the treatment of gastric ulcer would have attained the acme of perfection.

The Removal of Adenoids.—Dr. JOHN F. BARNHILL of Indianapolis described a safe and rapid method of removing adenoids. The selection of a proper curette having been made, an assistant took the child upon his lap and placed the patient's knees between his own knees, and thus clamped them as in a vise. The child's head was placed upon the left shoulder of the assistant, where it was firmly held between the two hands of a second assistant. Neither a tongue depressor nor mouth-gag was necessary. The operator sat on a chair facing the patient, who was requested to open the mouth. The curette was quickly inserted behind the palate, the posterior surface of which it should closely hug until the crest of the instrument pressed firmly against the vomer at its point of junction with the body of the sphenoid. In this position the patient's mouth must be opened to its fullest limit, and the curette would occupy a position in a plane about 45° to the horizontal, when the ample width of the fenestra surrounded the entire growth. Keeping the curette exactly in the center line of the patient's nasopharynx, the crest of the instrument was pressed firmly against the vault, in which situation it was quickly pushed backward and downward, the cutting blade closely hugging the entire base line of attachment of the adenoid, which was thus completely severed *en masse* and fell from the patient's mouth when the head was held forward for that purpose. In the majority of cases only twenty or thirty seconds were required to do the entire work after all was in readiness.

The Surgical Treatment of Some Inflamed Glands.—Dr. E. B. SMITH of Detroit urged the enucleation of inflamed suppurating glands. Where there was a hernia and the protruding tissue irritated a set of glands, then the hernia and not the glands must be cared for. Where the inflammation had progressed to the stage where resolution could not be brought about by poulticing, or where a simple incision would not effect a cure, and the tissue was broken down, or there was an accumulation of germs, then the only logical procedure was a radical operation. Glands found beyond hope of repair were excised, thus getting rid of a large number of germs, the remaining tissues being treated antiseptically and repaired. Repeated attacks of inflammation rendered the glands weak and susceptible to disease and suppuration. When glands were incised the inflammation and suppuration either subsided or became quiescent for a time, and then from a slight trauma became inflamed and suppurated.

Goiter.—Dr. GEORGE W. CRILE of Cleveland recently made a study of his cases of operations upon the thyroid gland, numbering 152, and he briefly summarized them from the standpoint of the practical management of the surgical thyroid. The development of the surgery of the thyroid is best appreciated by the statement that the mortality from thyroidectomy in simple goiters, in non-malignant, and benign tumors had fallen from 40 per cent. to a fraction of 1 per cent. In his own series, the last 101 such operations had been done without a fatality. The surgery of benign tumors and hypertrophies of the thyroid gland was now placed upon a basis comparable with that of appendicitis in the quiescent period, of gall-stones, and of ovarian tumors. The mortality from unexpected complications was perhaps one in one hundred or two hundred cases in the hands of a surgeon experienced in this line. Graves' disease was demanding much further investigation. Excision of the thyroid in Graves' disease broke a pathological chain and the cure was permanent. In a goiter under observation, if the gland began to grow, it should be promptly excised, because of the great possibility of its becoming a malignant growth. Many more thyroid glands should be removed, just as benign tumors elsewhere were removed, to prevent the appearance of a malignant growth.

Neuroses of the Bladder.—Dr. ROBERT C. M. LEWIS of Marion, O., considered a few of the neurotic conditions which were traceable to the genitourinary organs, especially those involving the vesical neck and the deep or prostatic urethra. In neurotic bladder troubles he gave first place to hyperesthesia because he believed it was met with more frequently than any other of its order. Mental worry or overtension of the nerves for a long period might produce a vesical hyperesthesia with a train of symptoms simulating a true cystitis; but, as a rule, if there were no inflammation, the absence of mucus or mucopus in hyperesthesia would give a line of distinction, so that cystitis might be excluded as a complication or as a sequel to other diseases of the bladder. There was found no other condition which gave so much mental and physical discomfort as hyperesthesia. Men were quite sensitive when it came to genitourinary troubles, but if a physician once

gained the confidence of such patients and afforded them relief they would not run away.

Intramural Transplantation of the Round Ligaments Versus the Alexander Operation or Ventro-Suspensio-Fixation.—Dr. CHANNING W. BARRETT of Chicago gave a résumé of the work done with intramural transplantation of the round ligaments, and, after comparing it with the Alexander operation and ventrosuspension, presented the following conclusions: (1) The Alexander operation fails because most cases of retrodisplacement are complicated. (2) An operation to be widely useful must open the abdomen for inspection and correction of complications. (3) It should be capable of being combined with the best incision for doing work. (4) It must not create false ligaments which will not evolute during pregnancy and involute thereafter. (5) There must be no abnormal arrangement of natural ligaments which allow them to run transperitoneally. (6) When the round ligaments are ample, the inner, stronger portion of the ligament should be chosen. (7) Operation for retrodisplacement must often be performed after much more operating, and so should not offer any tedious technicalities, such as are found in the external search for the ligament. (8) His internal inguinal shortening and transplantation of the ligaments through the abdominal wall was submitted for comparison with external shortening of the ligaments, or ventrosuspension operations, as one seeming to meet the essential requirements of an operation for retrodisplacements.

What We Cannot Do With Purgatives.—Dr. EDWIN WALKER of Evansville, Ind., said the action of purgatives was not well understood. Authorities varied widely as to how they affected the human organism. Practically all agreed that they were irritants. Purgatives and infections of the alimentary canal presented the same symptoms, namely, liquefaction of feces, increased albuminous exudate, the formation of gas and pain. The physician used purgatives in chronic constipation, when very few patients were in the least benefited, and nearly all were made worse. In obstruction of the bowels, both acute and chronic, they did harm, besides the time lost often decided the fate of the patient. The routine practice of preceding every surgical operation with a purge was absurd. If the operation was not on the alimentary canal, there was little reason for giving it. If it was on the stomach or bowel, they did not render the condition more favorable since they increased bacterial activity. The author had operated on nearly one thousand cases in which the preliminary purge was omitted. The results were as good or better than when they were given. The patients were more comfortable, and suffered much less with tympany. Laxatives were rarely required after operation, as the bowels would move as soon as it was necessary. Patients did better without them. Purgatives were useful, but should not be given in a routine manner. They should only be given when there were clear indications.

Perineal Section for Obstruction of the Prostatic Urethra.—Dr. CHARLES E. BARNETT of Fort Wayne, Ind., summed up the cause and effect of acute retention of urine. He considered catheterization more dangerous than operation. He believed that bladder drainage through a median perineal section was the operation of choice. Patients who were practically moribund recovered following improved operative technique with a minimum quantity of anesthetic, postoperative oxygen inhalation, Fowler's position, aspiration irrigation with large drainage tubes, and out-of-bed posture second day. Simplicity, but thoroughness, in the post-operative treatment was the desideratum. He reported several cases.

Early Diagnosis and Removal of Uterine Fibroids.—Dr. A. D. WILLMOTH of Louisville made a plea for the early removal of these growths. He expressed the opinion based on the statistics at hand and his personal experience that it was the duty of the surgeon to remove uterine fibroids as soon as they were diagnosed, unless some constitutional disease or diseases existed that made operative procedures inadvisable because of the risk involved, or where the surgeon had to deal with a young and childless woman who desired a child, or in those in whom the tumor was subperitoneal, small, and giving no trouble.

Treatment of Pus Tubes.—Dr. JOHN E. CANNADAY of Hansford, W. Va., said that operative and non-operative treatment had their separate and distinct fields. The trend was toward that form of conservatism which really conserved. Extreme and overconservative measures were as much to be deprecated as early radical extirpation, late and often. Surgical sense, judgment, ability, skill, and experience were needed, so that practically pus tubes should never be removed during an acute attack. Many cases would resolve and be restored to normal conditions by waiting. The author made a clinical classification of cases as follows: Those that resolved early, those that were followed by obliterating and crippling adhesions, and, finally, those in which large collections of pus were encapsulated and became sterile. In the latter class the best operative results were given. If the operative field was soiled with pus that was known not to be sterile a vaginal drain should be inserted, but not an abdominal drain, as the danger of wound hernia was too great. The author reported 100 cases in which laparotomy was resorted to for chronic pus tubes, with a mortality of one per cent.

Treatment of Inguinal Hernia in Children.—Dr. FRANK B. WALKER of Detroit said it was estimated that one-third of all herniæ occurred in children under fourteen years of age. In a series of 700 observations reported recently by Corner, it was noted that multiple herniæ were far more frequent in children than in adults. Premature children were very liable to hernia at birth, and inguinal hernia was presenet on both sides more often than at full term. From observations it would appear that the causes of hernia formation were more operative in earlier years than in adult life. He believed that it was good surgery to use conservative methods for hernia in children up to five years of age, and thought the majority could be cured thereby; but for the following class of cases, radical measures should be adopted: Strangulated hernia, irreducible hernia, hernia associated with hydrocele or undescended testis, hernia threatening strangulation, those which are uncontrolled or painful under truss treatment, and hernia in children over five years of age.

Postperitoneal Fibroid Tumors of the Uterus.—Dr. RUFUS B. HALL of Cincinnati reported cases and exhibited specimens. He had had a large number of postperitoneal tumors to remove. Some of the operations had been very complicated, while others had been comparatively simple. Some of these tumors were easily enucleated, even when large. By following the line of cleavage the surgeon was able to enucleate them without much difficulty. In others it often required great courage and skill to successfully remove them. Some were so firmly attached to the blood-vessels and ureters that to successfully remove them was practically impossible. Such a case occurred in the practice of Dr. I. S. Stone, in which he had the misfortune to lose his patient from hemorrhage before he was able to enucleate the tumor. In many of these cases the surgeon began the operation under the impression that he was going to remove a fibromyoma of the uterus. The tumor might be the size of an adult head, filling the pelvis full, and extending somewhat into the abdomen, or it might be very much larger. Even after the abdomen was opened and the tumor examined, it was not possible from the condition present to differentiate between postperitoneal fibromyoma and sarcoma. The author had made the mistake in beginning to enucleate a tumor, believing he had a fibromyoma of the uterus when in reality it proved to be a sarcoma.

Open Method of Treating Fractures.—Dr. DUNCAN EVE of Nashville said that in all cases in which marked comminution of the fragments was present, and when re-

duction was impossible, in oblique and spiral fractures of the bones of the extremities, operation was justified. Many of the deformities, pseudarthrosis, and loss of function which follow fractures would thus in many cases be obviated. The unsightly deformities which so seriously destroyed the usefulness of the part and predisposed to refracture would be prevented. Fractures complicated by severe injury to adjacent structures urgently demanded operation. Under this heading he included fractures in which pressure was brought to bear on neighboring viscera, nerves, and blood-vessels, fractures associated with dislocations, and fractures involving joints. By exposing the seat of fracture the accumulated excess of blood or effused serum could escape, and at the same time permitted the removal of any soft tissues that might be between the ends of the bone. In a case of comminuted fracture the surgeon could remove loose fragments of bone which had become entirely separated from their periosteal covering. The technique, after obtaining thorough cleanliness, was to make an incision sufficiently large to enable the surgeon to deal effectually with the fragments. The author reported two interesting cases. Operation should be deferred, if feasible, until after the acute symptoms of the primary injury had subsided, namely, from four or five days to a week. Operative treatment should be adopted in compound fractures: also in cases of a crippled fellow limb, of physical or business demands, of deteriorating personal discomfort, and of prospective activity of a perplexing nature, the wisdom of operation could well be considered. Prospective impairment of function and embarrassing delay in recovery invited the consideration of active interference. He was opposed, however, to the policy and the practice of those surgeons who operated only because a bone was broken and irrespective of present dangers or the future benefits to the patient.

The Opsonin Treatment in Gonorrheal Arthritis.—Dr. A. Ravogli of Cincinnati reported two interesting cases in which excellent results were obtained by the injection of gonococcic vaccine.

The following papers were also read: "The Differential Diagnosis of Duodenal Ulcer and Gallstones," by Dr. W. D. Haines of Cincinnati; "Operations on the Gall-Bladder," by Dr. Alex. C. Wiener of Chicago; "Internal Rotation and Lacerations of the Perineum," by Dr. George B. Twitchell of Cincinnati; "Plastic Tuberculous Peritonitis; Report of an Unusual Case," by Dr. Chas. H. Parkes of Chicago; "Plastic Work on the Urethra; A New Operation," by Dr. G. Frank Lydston of Chicago; "Sterilized Hands by Total Absolute Abstinence the Only Factor in Perfect Success," by Dr. J. Henry Carstens of Detroit; "Retroversion and Retroflexion of the Uterus, Causes, Consequences, and Treatment," by Dr. Hannah M. Graham of Indianapolis; "Gonorrhea and Marriage," by Dr. T. M. Reade of Springfield, O.; "Fracture of the Patella, with Report of Six Cases," by Dr. Robert Carothers of Cincinnati; "Delayed Union in Fractures," by Dr. Chas. Stoltz of South Bend, Ind.; "Torticollis, Some of Its Various Phases," by Dr. Reginald H. Sayre of New York City; "The Preparation and Post-Operative Care of Surgical Cases," by Dr. L. G. Bowers of Dayton, O.; "The Surgical Treatment of Acute Intestinal Obstruction and Report of Cases," by Dr. W. A. Melick of Zanesville, O.; "Volvulus of the Entire Mesentery of the Small Intestine, with Report of a Case," by Dr. C. E. Briggs of Cleveland; "The Sigmoidal Factor in Pelvic Diseases," by Dr. J. Rawson Pennington of Chicago; "Internal Strangulated Hernia," by Dr. E. M. Brown of Chicago.

(To be continued.)

Fumes of Burnt Sugar as an Antiseptic.—According to the *American Druggist*, M. Trillat of the Pasteur Institute has found that formic aldehyde is given off by burning sugar and that the fumes produced are therefore antiseptic and deodorizing.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 17, 1907.

The President, Dr. John A. Wyeth, in the Chair.

The Mosquito as a Sanitary Problem.—Dr. Edward A. Ayers delivered this, the Wesley M. Carpenter lecture. He said that mosquitos were a necessary factor in the production of malaria, yellow fever, and filariasis in man; so far as was known they were the only factor involved. Recent investigations had brought dengue and beriberi into the list. Several hundred thousand human beings were annually killed through mosquito infection, and many millions injured in health. The prevention of mosquito infection of man was one of the simplest problems in the list of infectious diseases. The extermination of mosquitos was wholly feasible, the methods sufficiently understood, the accomplishment well within the financial capacity of every nation; yet but an infinitesimal portion of the work had been undertaken. Therefore, the mosquito as a sanitary problem was one of the most attractive and urgent medicopolitical issues of the day. It was the best known, the least applied, and the most promising field now open to organized medicine.

The Life History of Mosquitos.—The mosquito, by reason of its ubiquity and skin-piercing capacity, was the king of the insect world; and while other insects annually destroyed some $800,000,000 of lumber, grain, and fruit in the United States, the mosquito destroyed human health, lives, and property values combined. In her immemorial time she had destroyed more human beings than existed to-day. She approached this result nearly every five hundred years. One healthy favored pair of early June mosquitos could start a progeny that would rival the human population of the globe in numbers ere the harvest moon; yet one man with a spade could destroy more prospective mosquitos in an hour than mankind numbered at any one time. A pregnant mosquito, caught in the sudden congelation of a drop of dew, could peacefully sleep through the wintry months, and when the spring sun set her free could lay four hundred hatchable eggs. Over five hundred mosquito families had been classified, and still the work was incomplete. The mother mosquito deposited from fifty to four hundred eggs at a single accouchement. The wriggler would starve in distilled water, yet could stomach more antiseptics than we could safely swallow. It hated kerosene more than carbolic acid only because the former films the water's surface and gets into its caudal throat when seeking air. Ungilled, like the whale, it must inhale the air at intervals. Extending from one side of its caudal end was a hollow tube which it pushed up to the air, and once there it had sufficient air-grip to hold it effortless. Through this ventilating shaft the larvæ could respire at their ease. They spent most of their time hitched to the air, swinging head downward, securing such food as might move within their limited radius. With their ciliary whiskers they could bring débris to their mouths. At the end of a week the larva should measure about three-fifths of an inch from mouth to siphon tip. The larvopupal transformation was one of the most startling "quick-change" performances ever witnessed. As a pupa it could see, breathe, and swim, but no food could pass its lips, for it had none, nor would have for forty-eight hours, during which time it must fast. The male had long palpæ and bushy antennæ; the female short palpæ and thinly-haired feelers, an exception occurring in the female anopheles, which had long palpæ. The life obligation of the male was defloration, and its penalty death. The male made use of his whiskered antennæ in finding a mate. Within a couple of days the widowed mother mosquito would deposit her eggs. The culex and stegomyia were much alike, the former when standing being more hunched, with lower head, wings, and body The axis of the anopheles ran upward from head to fundament. The wing song of the culicidæ and stegomyia was

of higher pitch than that produced by the anopheles. Contralto in culicidal tone production meant malaria.

The Mosquito as a Carrier of Disease.—Through two thousand years suspicion was held that mosquitos were responsible for malaria in man. In 1863, Demarquay reported the existence of a minute smooth worm, afterward called *Filaria sanguinis hominis*, in a case of chylocele in a resident of Havana. This nematode proved to be an embryo filaria, its adult form being discovered by the elder Bancroft in 1876. After giving a description of the filariæ, he told of the mosquito's part in filarial development. Sir Patrick Manson, having allowed mosquitos to bite filarial subjects, observed the presence of the ensheathed filariæ in the viscous blood sucked into the insect's stomach; saw them drive their bodies head-first against their sheaths, rupture them, and escape. He saw these filariæ bore through the stomach wall and wander through the muscles of the chest, and other parts. Bancroft further demonstrated their migration into the proboscis of the mosquito. . As to malaria, its cure was discovered two hundred and forty years before we knew what was cured. The speaker then described the life cycle of the malarial parasite. Nott, of Mobile, in 1848, charged the cause of yellow fever to mosquitos. The deplorable death of Jesse Lazear from accidental inoculation; the premature death of Walter Reed from gangrenous appendicitis originating in profound bodily exhaustion; the physical and other trials of James Carroll, but recently advanced in rank by Congress, only to die within the year; these were familiar features of the final death-grapple with yellow fever. After telling what the Reed Commission proved, he said that in the forty-seven years preceding 1900, 35,952 residents of Havana died from yellow fever, a constant mortality of one in every ten of her inhabitants. Under the vigorous control and activity of Colonel Gorgas, yellow fever was completely exterminated in ninety days. Havana's yellow fever chart from 1881 to 1901 showed an average annual mortality of 449. In achieving its notable victory through its agents, our Government had incurred a demonstrated obligation to complete what must constitute the fourth act of our sanitary drama—prevention of all diseases of this sort by extermination of the insect.

The Extent of Mosquito-spread Diseases.—According to Jackson, the filarial worms were in the blood of from 10 to 50 per cent. of the people of the tropical and subtropical portions of the globe. Wherever mosquitos existed, malaria occurred. In the United States census it was stated that 18,594 deaths were charged against malaria in the year following May 31, 1889. During the next ten years the death rate fell from 19.2 per 100,000 to 8.8 in the registration area, which was about one-third the whole. In Italy the mortality during the last few years had fallen from over 15,000 to 4,700. During the past one hundred years, 100,000 people died from yellow fever, and some 500,000 were infected.

Extermination of Mosquitos.—That extermination was feasible, economical, and less difficult than was generally supposed, was unquestionable. Mosquitos could breed successfully in swamps, small streams, shallow-shored lakes, ponds, puddles, water tanks, cesspools, stable pits, rain barrels, and all water-filled receptacles which remained unchanged a fortnight. Their destruction was chiefly accomplished by drainage of all standing-water areas, or by leading the "small fry" fish to the larvæ and pupæ in parts which cannot be kept dry. The New York Legislature of 1905-6 passed a special act, the de Groot Bill, which gave Boards of Health power over private mosquito factories. The great swamps of Elizabethport and Hackensack, in New Jersey, were being dried mostly by 10x30-inch ditches. The ditching machine now used in New Jersey cost $25 per day, and cut 10x30 or 20x30-inch ditches from 2,000 to 3,000 feet per day. One man could keep 75,000 feet of ditches in proper condition from year to year. Extensive plans for the construction of an inland water route for vessels of considerable draught along our entire Atlantic coast from Buzzard's Bay to Florida were under way, and when completed would help drain many hundred thousand acres of swamp land. The drainage of swamps for mosquito extermination should be incidental to permanent agricultural reclamation. A slap at the mosquito for the moment, kerosene for the week, ditching for a season, but reclamation for all time! New Jersey was well under way in the drainage of her 200,000 acres of swamp land, and had dug over a million feet of ditches and largely drained the Elizabethport, Hackensack, and Newark meadows. Long Island had some 50,000 mosquito acres weighing down the efforts of her land boomers. Staten Island had received radical treatment. Even New York, crowded Manhattan, was ridiculously infested with mosquitos. The Government hospitals in the Philippines were largely unscreened, and much needless mosquito infection went on. The mosquito as a sanitary problem should no longer exist. The mosquito was a political problem; its widespread existence had become an anachronism; its extermination was a problem for the civil engineer, a calculation of cost, in the case of dollars *vs.* ditches. This was the issue that twenty-seven years of unparalleled scientific achievement presented to statesmanship. The yellow fever epidemic of 1878 cost not less than $100,000,000. The loss to New Orleans was over $10,000,000, while nearly $5,000,000 relief money was poured into the stricken cities of the South. The epidemic of 1897 cost the Southern Pacific $1,000,000. With the money loss equivalent every State on the Gulf of Mexico could have been rendered mosquito-proof, with enough left over to have rivaled the treasury balance of to-day. Onslaught against political sanitary inertia was to-day the most promising field open to organized medicine.

SECTION ON MEDICINE.

Stated Meeting, Held October 15, 1907.

DR. WARREN COLEMAN IN THE CHAIR.

Report of a Case of High Arterial Tension Relieved by Treatment.—Dr. L. F. BISHOP reported this case. Several years ago he said he was impressed with the importance of hygienic measures in the control of high arterial tension. He had also been impressed with the proper use of drugs and the influence of the brain over peripheral circulation. He referred to high arterial tension and *not* to high blood-pressure. The patient was a man, sixty years old, who had been suffering from various symptoms for ten years and who had been told by several physicians that he was suffering from high arterial tension. Nine years previous he had had a slight attack of paralysis, accompanied by aphasia, from which he gradually recovered. When Dr. Bishop first saw him he was suffering from severe headaches, and became tired on exertion. His bowels were constipated and he was over weight. The blood-pressure readings were high. He was said to be suffering from neurasthenia of chronic form, complicating high blood-pressure, which was supposed to be the result of kidney disease. He had been treated by rest in bed, nerve tonics, and nitroglycerin. As a cause of his trouble excess of application to his affairs, with a marked tendency to worry, was evident. There was a feeble and dilated heart, with a soft systolic murmur, with irregularity in force and rhythm. The pulse was hard and incompressible. There was shortness of breath on exertion, and inability to walk without a feeling of increased tension in the head. The red cells numbered nearly six millions and the hemoglobin was 100 per cent. The urine showed albumin and casts, but the specific gravity was not much lowered. The neurological examination showed the usual signs of a slight, old, right hemiplegia. Dr. Bishop cut off all tonics and reduced the diet, prohibiting sugar absolutely, also wine, and meat except once a day. He ordered the patient to exercise

up to the point of soreness of the muscles. He used suggestive therapy by long conversations with the patient, attempting to instil the idea of the possibility of recovery and the necessity of eliminating worry. He combined 1/200th of a grain of nitroglycerine with digitalis. During the first two months the progress of the case was slow and most discouraging, the patient being relieved only at times. About the third month the patient's blood was found to contain 4,872,000 red cells, 8,440 white cells, and 95 per cent. hemoglobin. The weight had been reduced about six pounds, and all sense of fatigue had disappeared. Three months later the patient had still improved. Nine months after treatment was begun there was very little tension and the patient felt well, was able to enjoy life as he had not enjoyed it in ten years. He then ceased to regard himself as an invalid. The plan of treatment pursued in this case was best described by the term adopted by Dr. Barker, "Reeducation." The high arterial tension was due not so much to any pathological condition as to errors in physiology, and when these errors were corrected by training the hypertensity disappeared.

Case of Paranephritic Abscess.—Dr. Robert H. Halsey reported the case of a driver, twenty-two years old, single, who came to the dispensary complaining of pain in the left side of the abdomen extending across the back, and a general weakness. The previous history was without value, excepting for a gonorrheal history ten years ago, and a second attack eight weeks before appearing at the dispensary. He had syphilis in 1905 and he was still on iodide of potassium. The pain commenced four weeks before in the left lumbar region and remained practically the same until about four days before coming to the dispensary, when it passed to the right side. It was less severe in the morning. The appetite was poor, the bowels constipated, and during these four weeks of pain he lost eleven pounds. His heart and lungs were negative, pulse was good, and glands enlarged. There was no muscular rigidity of the abdominal muscles. Deep pressure in the left hypochondrium elicited a reflex spasm of the muscles, so that no mass could be made out. The temperature was 103°, pulse 88, respirations 26. When he entered the hospital his temperature was 104°, pulse 116, respirations 34. The temperature remained high for the first week. During the second week there was a distinct morning remission to about 100°, with an afternoon rise to 102°. The pulse remained about 80, respirations 20. The erythrocytes were about 4,800,000; hemoglobin about 75 per cent.; leucocytes about 14,000; polynuclears about 78 per cent.; lymphocytes about 14 per cent., and eosinophiles about 4 per cent. The blood picture remained the same with the leucocytes varying between 15,000 and 22,000 until after the operation, when they dropped to about 7,000. There were no casts, albumin, or indican in the urine. The specific gravity was about 1,018 and the quantity in twenty-four hours about 900 c.c. The seven twenty-four-hour specimens before operation showed a trace of albumin, indican, and few hyaline casts. The sixteenth day after admission it was thought wise to perform a cystoscopy, which was done by Dr. James Pederson. Ten days after admission the man developed spasm of the left psoas muscle, which prevented complete extension of the left thigh. The pain persisted in the left side. Until the seventeenth day nothing abnormal was noticed or felt; but on that day a slight bulging appeared in the left lumbar region just below the ribs. Dr. E. W. Peterson was called in consultation and agreed that a retroperitoneal abscess was probably present. Operation by incision was performed and a large amount of pus evacuated. The location of the abscess was evidently external to the psoas and behind the peritoneum. The lower border of the left kidney could be felt above the abscess cavity. The day after the operation there was a rise in the temperature to 102°, but it soon fell to 98° and remained there. The recovery was uneventful, and while on the day of operation his weight was 133 pounds, on the day of his discharge it was 152, a gain of 19 pounds. An interesting feature was the probable path of the infection. While the ureter and bladder were free from any infection, the lymph nodes undoubtedly were the path by which the infection traveled to the deep lumbar glands, those lying upon the psoas muscle being evidently the most vulnerable, and enlarged because of his syphilitic infection, and superadded gonorrheal infection was too great, and an abscess formed. In reality it might be called a bubo beneath the left kidney. The complete absence of any irritation of the kidneys at any time during the severe infection was worthy of note, especially since complications from gonorrheal infections most frequently travel by means of the bladder and ureter.

Demonstration of Kuhn's Lung-Suction Mask for the Hyperemic Treatment (Bier) of Pulmonary Tuberculosis.—Dr. Willy Meyer read this paper. (See page 757.)

Dr. Charles E. Quimby said it interested him to see an audience in New York listen to a paper on the physical treatment of tuberculosis of the lungs. This was not Bier's treatment and had no relation to it. The suction method could not be claimed by Bier; he had no claims whatever. Bier used passive, obstructive hyperemia. For twenty-two years there had not been a day hardly that Dr. Quimby had not had a patient under his treatment by atmospheric means for producing changes in the pulmonary circulation. Fifteen years ago, after eight years' experience, he stated before an association that there was no method at one's disposal so valuable in the treatment of pulmonary tuberculosis as the modification of the circulation by atmospheric pressure. He said he had been laughed at during these years, and he had had men say that he knew absolutely nothing about it, that the treatment was no good. Bier's method by the use of the mask and Dr. Quimby's method had no relation; they were entirely different. He wished to repeat what he said fifteen years ago and after thirty years' experience and close knowledge of what had been done in this country, and particularly in the treatment of tuberculosis, that there was no method at our disposal to-day which was equal to the pneumatic cabinet, a method of differential atmospheric pressure, in the treatment of lung disease. There was no one treatment for tuberculosis. Bier's treatment was a mechanical hyperemia, an obstructive hyperemia. It produced increased flow of blood to a part. He showed that tuberculosis of the joints improved under this treatment. Why did it improve? The conditions produced were an increased amount of blood to the part, an increased pressure, and a slowing of the circulation. But no man, he said, could convince him that slowing the circulation was good for anything in any reparative process. He would not say that increase of blood to a part would not help, but he was in doubt whether an increased amount of blood plus the slowed circulation was of value. This slowing of the circulation and increasing the pressure injured the tissues. In other words, this plan was exactly the same, only in another form, as the use of tuberculin, it was a localized irritant. Dr. Quimby said that the essential element of the injurious action of the tubercle bacillus was that it did not make a disturbance, did not irritate the tissues. When one took a tuberculous joint, and filled it with blood and injured it, then there was produced a condition demanding a reparative process. The value of Bier's treatment was in producing this injury of the tissues. When the bandage was removed, the circulation set in and repair was attempted. If one pulled and injured fibrous tissue and then let it alone, nature would remove a little bit of the injured tissue; repeating the injury would cause an absorption of this fibrous tissue. If one continued to irritate the fibrous tissue, nature would build it up and get the better of one in spite of everything. With regard to the suction hyperemia, he said that Bier had no claim to it. When Dr. Quimby was a boy he remem-

bered seeing an apparatus for treating the eye by suction. He had followed the development and application of the so-called Bier's treatment. No man had any right whatsoever to compare it with the obstructive treatment. It could not have the same effect upon the lungs as it had upon other parts. As to hyperemia he believed that there was no one thing that did so much good. Hyperemia under suction must be hyperemia with increased pressure in the lungs, and he asked if that was desirable? He did not know. The process by which one got the blood to the lungs was important. He had used this treatment for pulmonary tuberculosis for twenty-five years. An increased pulmonary circulation, with an active and persistent hyperemia, a hyperemia accompanied with an increased circulation, was a method which in his experience had no competitor to-day in the treatment of pulmonary tuberculosis.

Dr. A. Jacobi said that he had had no personal experience with Bier's treatment, either in medical or surgical cases. The amount of circulating blood in the lungs, however, had much to do with the predisposition to tuberculosis, or to relative immunity. It had already been said that it was known that when the nutrition of the lungs had suffered by anemia, tuberculosis was very frequent in those lungs. Thus if one had a congenital smallness of the lungs, the lungs would be in a condition of undernutrition; then tuberculosis might take hold. If one was dealing with a congenital or acquired pulmonic stenosis, there was a condition of anemia and undernutrition of the lungs, and tuberculosis very frequently resulted. In this way a great many of the subjects of congenital cyanosis, or cyanosis due to obstruction of the pulmonary arteries, died of tuberculosis. On the other hand, it had been known when there was some heart lesion that resulted in obstruction in the veins then there was little tuberculosis following. Many observers had made the statement that valvular disease of the heart and tuberculosis did not go together. Thus it appeared that if the lungs were in a condition of venous obstruction there should be but little or no tuberculosis. The records from the Phipps Institute this year showed that only two per cent. of the cases of tuberculosis at autopsy had stenosis; that almost excluded tuberculosis of the lungs in venous hyperemia. If that was so, he asked if it was not natural to provide a venous hyperemia in order to prevent or to retard the progress of tuberculosis. If the inhalation mask did that, it was a good addition to our means of combating tuberculosis. Tuberculosis could not be cured by any one method; if one attempted to do so he would fail. He believed this method would do much good and should be given a trial. He only feared that the apparatus would fall into the hands of patentees.

Dr. Haven Emerson said that one must accept the fact that increasing the negative pressure caused an increase of blood flowing through the lungs. It facilitated the flow of the blood from the lungs to the right side of the heart. Therefore, it was a true hyperemia and not a venous condition with obstructed entrances. They understood that the increase of volume and increase of blood pressure was due to negative thoracic pressure and increased flow of blood to the right side of the heart. If one periodically increased the negative pressure, just so much did he increase the volume and flow of blood through the lungs and the general arterial pressure. A low blood pressure was characteristic of tuberculous affections. They were improving the character of the general circulation by increasing the blood flow from the left to the right side of the heart.

Dr. George Mannheimer said that in the reports from Berlin, showing the x-ray pictures of patients during ordinary and mask breathing, the condition in the lungs did not show so well in the former as in the latter. He did not believe, however, that the mask treatment of the lungs would do as well as Bier's treatment of tuberculosis of joints or other parts. From his own limited experience he did not know whether the mask did good or not.

Dr. L. Rosenberg, Medical Superintendent Montefiore Home Country Sanatorium, said that after eight months' use of the mask he had two very salient things to say. First, its use increased the moisture in the affected lungs; secondly, it produced a reduction in the blood pressure, usually from twenty to thirty millimeters. So far as he could determine it had no effect upon the blood picture. In one case he used the mask when there were attacks of copious hemoptysis. In that case it did not induce fresh attacks, and the patient was doing well. It did not seem to do harm in those cases where there was a tendency to bleeding. The experience at Bedford was too short to enable him to offer any deductions as to the value of the mask.

Dr. S. A. Knopf believed one should be cautious in the use of any new remedy. He had had occasion to watch the effects of Bier's treatment in surgical tuberculosis and he became very enthusiastic because it prevented a number of operations. On the other hand, he had not seen anything remarkable from the use of the mask as yet. The reasoning would seem to indicate at present that this physical means, if judiciously applied, would help. He was inclined to believe that the patients, after wearing the mask for a while, would have a strong desire to breathe naturally, and take deep inspirations, filling the system with better air, so that they would feel better on account of the deep inspirations.

Dr. Willy Meyer said that after his return from Atlantic City, in June, where he had read a paper on Bier's treatment before the Surgical Section of the American Medical Association, he had written Dr. Alfred Meyer and Dr. George Mannheimer to test Kuhn's mask at the Bedford Sanatorium. Not having heard from them, he thought they had not followed the suggestion. Had he known that they had meanwhile gathered some personal experience, he would not have ventured to discuss a subject which properly belonged to the medical man. With regard to Dr. Quimby's statement, he did not believe it to be wise to go into a discussion on the theory of the hyperemic treatment. Bier and others had proven beyond a doubt that by using this method surgical tuberculosis could be cured. He could, therefore, not see any reason why the same procedure, if properly applied, should not prove of equal benefit to pulmonary tuberculosis. That this treatment injured tissues he did not believe. With regard to the effects of higher altitudes it rapidly increased the number of red and white blood corpuscles, as well as the percentage of hemoglobin. This same was done by the use of the mask. In other words, it was possible now to benefit the patient by the use of the mask in the valley as much as by sending him to some higher altitude, at least to a certain extent. Dr. Meyer then presented a patient with the mask to illustrate its application and method of using.

A Brief Report of Further Experiments in the Use of Parathyroid Gland for Paralysis Agitans.—Dr. Wm. N. Berkeley read this paper. He said that the curious and remarkable symptoms following complete parathyroid excision were now familiar. The animal operated upon began in about twenty-four hours to show enormously hurried respirations, tachycardia, profuse salivation, constant twitching and shivering of voluntary muscles, rigidity, and intermittent convulsions; he refused food, wasted rapidly, and within a few days died, quite often during the convulsive seizure. The essential metabolic chemistry of the process was quite unknown. It was presumed that the gland secreted something itself essential to the organism or something antitoxic to irritant waste products formed elsewhere, or perhaps something complementary to the secretion of the thyroid gland. The close proximity of the parathyroids to the thyroid in all vertebrates so far examined lent some color to this last hypothesis, but

other guesses could be made as well, and a fast line should be drawn between conjecture and proved truth. Was there any disorder of the human frame, analogous to exophthalmic goiter, owing its origin to diseases of the parathyroid glands? This was a subject for experimental clinical study. Over two years ago the Swedish neurologist, Lundborg, and the speaker, independently and along different lines of reasoning, formed the notion that paralysis agitans was the disease, or one of the diseases, in question. Dr. Lundborg's paper antedated his by nearly a year. Avoiding questions of priority the paper meant to set forth briefly some further work on paralysis agitans which had brought forth some new facts and seemed worth writing about. He considered (1) laboratory work, (2) autopsy findings, and (3) clinical results from administration of the gland. It had been possible to prepare from carefully identified ox-gland a highly concentrated parathyroid nucleoproteid for use in hypodermic form. The action of this proteid on dying parathyroidectomized dogs was marvelous. It unquestionably contained a large portion of the principle of the gland. He pulverized and preserved the entire gland. The preparation so obtained was dispensed in capsules, each capsule corresponding to one-half of one fresh ox-gland. Three to five capsules were given each day. The dose for hypodermic injection was 0.5 c.c. per day. It worked better under the skin than in muscles. Veins should be avoided with special care. It was now possible to collate twelve recent autopsies made upon cases of Parkinson's disease in which the parathyroids were objects of special research. Of these nine were reported on by R. L. Thompson, two by C. D. Camp, and one by himself. Thompson concluded that there was no morphological ground for the assumption that the parathyroids were insufficient in paralysis agitans. His own case, on the contrary, showed a definite degree of destructive sclerosis, but whether enough really to embarrass the function of the glands it would be impossible to say. No definite conclusions could be drawn from the reports on these twelve cases. But it should be noted that the histology of the glands of internal secretion generally gave only a very elementary notion of their function. After emphasizing the importance of having a properly identified gland, he said that nothing much in the way of favorable results could be hoped for except from relatively small doses continued through a long period of time. The extremely chronic way in which the disease approached would seem to indicate that slow regression of the bad symptoms should be the rule. Again the temperaments of these patients were somewhat modified, they being easily depressed, easily encouraged, subject to changes of opinion, etc. The results of treatment in his own cases, as well as in the cases of friends and helpers, were given. He had notes or personal knowledge of thirty cases. Of these, two patients declined to continue the treatment; two had not been heard from; five denied any benefit; three showed temporary improvement, and eighteen were progressively benefited during the entire period in which they were under treatment. The benefit consisted in diminished rigidity, lessened pain, cure of salivation, shaking diminished or cured, voluntary control of muscles greatly increased, and restlessness and insomnia almost abolished.

Dr. S. B. Beebe said that but little was known regarding the glands which furnished the internal secretions; no one could successfully controvert that fact. As to the relation of the parathyroids to disease he said he was unable to make any definite statement. But as to the relation of the parathyroids to the condition called tetany, there was a close and definite relation, the relation of cause and effect. This condition was due to the removal of the gland and not to any traumatic injury to the nerves; it was a disturbance caused by the removal of the parathyroid gland. Just how it acted was as yet undecided. Whether it neutralized the toxins or acted as a sedative in itself was a difficult matter to settle. But the evidence we had, so far as we had gone in the study of this matter, indicated that the parathyroids did neuralize or help to eliminate toxic substances which appeared in the course of metabolism. He was inclined to believe that this toxic substance came from the metabolism of proteid foods. We knew that histologically the gland nuclear material and cells were much more prominent in the parathyroids than in the thyroids. Little globulin was found in the parathyroid gland. When the parathyroids were removed, one got symptoms of tetany, which the hypodermic injection of this nucleoproteid of the gland relieved at once. It was impossible to get this relief by any other part of the proteid content of the gland. Administering this organic product by the hypodermic method was the most physiological way of doing it. He had found that the gastric digestion of these proteids, when given by the mouth, rendered them less efficacious in relieving the symptoms of tetany. It did not completely inhibit the power, but required considerably larger doses to get the same effect.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Wisconsin Board of Medical Examiners.

Milwaukee, January 8-10, 1907.

OBSTETRICS.

1. Name the external and internal female organs of generation and describe the uterus.
2. Name the positive signs of pregnancy and at what time they can be recognized. Name the doubtful signs.
3. Name and describe the different stages of normal labor and your management in each stage.
4. Differentiate ascites, ovarian cyst, and pregnancy before the fifth month.
5. Give symptoms and treatment of albuminuria of pregnancy, and treatment of eclampsia.
6. State the danger of a prolapsed funis and give treatment.
7. Name the causes of antepartum and postpartum hemorrhage. Give treatment of each.
8. What are the indications for the use of the forceps? Give rules for applying them.

GYNECOLOGY.

1. Give causes, symptoms, physical signs, and treatment of cervical endometritis.
2. Give etiology, symptoms, physical signs, and treatment of pelvic cellulitis.
3. Define ectopic gestation, name varieties, give diagnosis, prognosis, and treatment.
4. Give etiology, prognosis, and treatment of membranous dysmenorrhea.

SURGERY, LARYNGOLOGY, OPHTHALMOLOGY.

1. Define acute bursitis and synovitis and give treatments.
2. Describe Bassini's operation for the radical cure of inguinal hernia.
3. Define Raynaud's disease and noma and give treatments.
4. Define tumors, name varieties, and give prognoses and general treatment.
5. Name varieties of bone diseases and give treatment of osteomyelitis.
6. Define a fracture and give the treatment for a fractured patella.
7. Define a dislocation and name and give treatment of elbow varieties.
8. Define actinomycosis and tetanus and give treatments.
9. Define perichondritis and chondritis and give etiology and treatment.
10. Describe operations of intubation and tracheotomy and tell when indicated.
11. Define ophthalmia neonatorum and give treatment.
12. Define trachoma and give etiology and treatment.
13. Define iritis and keratitis and give etiology and treatments.

HISTOLOGY, BACTERIOLOGY, AND PATHOLOGY.

1. (*a*) Name the fundamental groups of tissues and

give an example of each. (*b*) Describe the stages in cytomorphosis. (*c*) Give differential diagnosis of a section of stomach, duodenum, ileum, and colon.

2. (*a*) Describe minutely the intima of a medium sized artery. (*b*) Describe the mucous membrane of the bladder. (*c*) By diagram show the normal histology of a lobule of the lung.

3. (*a*) Stain for tubercle bacillus in sputum and give two other bacteria that behave similarly to the stain. (*b*) By culture differentiate *Bacillus typhosus* from *Bacillus coli communis*.

4. (*a*) Name four pus-producing bacteria. (*b*) Describe and explain the Widal phenomena. (*c*) How would you demonstrate gonococci in a urethral discharge?

5. Give the gross and microscopic appearances in fatty degeneration of the heart.

6. Give the reasons for the following phenomena in inflammation: (*a*) The decreased velocity of the blood. (*b*) The formation of border zones.

7. Explain how infarcts are formed and tell where they may be found in the body.

8. Give the steps in the formation of a thrombus, describe its organization; where will it not organize?

9. Classify neoplasms of epithelial origin and describe one.

10. Give the structural changes in a liver lobule found in a case of atrophic cirrhosis.

11. Give the pathology of locomotor ataxia.

12. Discuss waxy degeneration.

NEUROLOGY.

1. Name the ganglia connected with the fifth pair of cranial nerves.

2. Give the origin, principal branches of the median nerve, and its distribution.

3. What is the function of the trochlear nerve?

4. How is the sensation of sound conveyed to the brain?

5. Define the process of cerebral softening.

6. What part of the cord is involved in locomotor ataxia? Progressive muscular atrophy?

DIETETICS.

1. What influence has the nervous system on gastric digestion?

2. Give classes of foods and describe their effect upon the body tissue. Describe metabolism.

3. What should be the diet of a child two years old?

MEDICAL JURISPRUDENCE.

1. When is abortion justifiable?

2. Differentiate between civil and criminal malpractice.

3. What constitutes expert testimony?

ANATOMY.

1. Give names and functions of cranial nerves.

2. Describe the gall-bladder and bile ducts.

3. Name the salivary glands and give their locations.

4. Describe ankle joint and name bones entering its formation.

5. Give the minute anatomy of the kidney.

6. Name and give function of muscles moving the eye ball.

7. Name, locate, and describe valves of the heart.

8. Describe the circle of Willis.

PEDIATRICS.

1. Give the principal causes of infantile convulsions.

2. Give the symptoms and course of an ordinary case of tubercular meningitis.

3. Of what does spina bifida consist?

4. Tell what you know of what is commonly known as membranous croup.

MATERIA MEDICA AND THERAPEUTICS.

1. What is the source and composition and what are the preparations of ipecac?

2. Name the agents affecting the organs of vision when locally applied, illustrating their action and use.

3. What are the principal agents acting on the circulation? Classify them in groups according to their action and name the members of each group.

4. What are escharotics, astringents, styptics, and emollients? Name the principal drugs belonging to each group.

5. What are the principal digestion ferments, where are they obtained, and what are the actions of each?

6. How would you treat a case of poisoning by iodine?

7. What are the preparations, doses, physiological actions, and therapeutics of belladonna?

CHEMISTRY, TOXICOLOGY, URANALYSIS.

1. Define the term "an alkaloid."

2. Define the term "a chemical radicle."

3. Define and give examples of the terms, "acids," "bases," and "salts."

4. State the formulæ and some of the medical uses of nitric and hydrochloric acids.

5. Explain the meaning of the prefixes "hypo" and "hyper" as applied to chemical compounds.

6. State the reaction which occurs when a solution of potassium iodide is mixed with a solution of mercuric chloride.

7. Give the chemical symbol for the element sodium and describe three of its principal oxides and salts.

8. Give characteristic symptoms and treatment of strychnine poisoning.

9. Name the most common sources of lead poisoning, symptoms, and treatment.

10. What are the characteristic symptoms and treatment of corrosive sublimate poisoning?

11. Give the average composition of normal urine, including specific gravity and reaction.

12. Describe tests that you would employ to detect albumen, sugar, and an excess of urea in the urine.

PHYSIOLOGY, HYGIENE, AND PHYSICAL DIAGNOSIS.

1. Give the functions and describe the pneumogastric nerve.

2. Describe the phenomena and give some of the theories of sleep.

3. Describe the mechanism of respiration, both normal and forced.

4. What effect does diet have on the secretion and constituents of milk?

5. Give the products of intestinal digestion and state the disposition made of these products.

6. Give the properties and functions of the medulla oblongata.

7. (*a*) Give function of the thyroid body. (*b*) What effect does its removal have?

8. What precautions are necessary and what is the length of quarantine of (*a*) variola, (*b*) scarlatina, (*c*) diphtheria, (*d*) yellow fever?

9. Give general outline for disinfection and fumigation. Name materials used.

10. Give the differential diagnosis of hepatic colic and appendicitis.

11. Give diagnosis of cardiac hypertrophy affecting (*a*) the left ventricle, (*b*) the right ventricle.

12. (*a*) How would you diagnose cerebral hemorrhage? (*b*) What are the most reliable signs of death?

PRINCIPLES AND PRACTICE.

1. Give differential diagnosis of gastric ulcer.

2. What is spinal sclerosis, its varieties and pathological anatomy?

3. Give differential diagnosis and treatment of pleurisy with effusion.

4. Name four diagnostic facts which can be determined by chemical and spectroscopic examination of feces, giving the test for one of them.

5. Give etiology and pathology of hemiplegia.

6. What is autointoxication? Give the source of the toxins producing this condition.

7. Give diagnosis and treatment of chorea.

8. Give etiology of tuberculosis. What measures in your judgment are best in preventing the spread of this disease?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

WISCONSIN BOARD OF MEDICAL EXAMINERS.

Milwaukee, January 8-10, 1907.

OBSTETRICS

2. *Positive signs of pregnancy.*—(1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

The *positive* signs can all be recognized at the end of the fourth or beginning of the fifth month.

Doubtful signs of pregnancy.—(1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

4. *Ascites.*—Absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides, the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies with the position of the patient.

Ovarian cyst.—Absence of the chief signs of pregnancy; there may be the characteristic facies; the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

Pregnancy.—The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health, may also help in arriving at a diagnosis.

6. *The danger of a prolapsed funis* is asphyxiation of the child from compression of the cord.

Treatment consists in: (1) Not rupturing the membranes prematurely, unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually, or with some form of repositor; (4) speedy delivery, by forceps or podalic version.

8. *Indications for the use of forceps* are: "1. *Forces at fault*: Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault*: Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault*: A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications*: Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both." (From Jewett's *Practice of Obstetrics.*)

Conditions necessary for the use of forceps are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

GYNECOLOGY.

3. Ectopic gestation is a pregnancy in which the ovum is developed outside of the uterine cavity.

Varieties.—Ovarian, tubal, interstitial, abdominal.

Diagnosis.—"When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetrics.*)

Prognosis.—All forms of ectopic gestation are exceedingly dangerous.

Treatment consists in the removal of the product of conception, by a laparotomy, as soon as the diagnosis is made.

4. MEMBRANOUS DYSMENORRHEA. *Etiology.*—Interstitial endometritis.

Prognosis is not so good as in the other forms; as the condition is obstinate, the prognosis must be guarded.

Treatment consists in curettage, which may have to be repeated (perhaps more than once) before a cure is effected.

SURGERY, LARYNGOLOGY, OPHTHALMOLOGY.

11. Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the newborn, due to the gonococcus or other pyogenic germ; produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

The treatment is (1) *Prophylactic.*—Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial.*—Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

12. *Trachoma* is an inflammatory condition of the conjunctiva, accompanied by hypertrophy, granule formation, and subsequent cicatricial changes.

Etiology.—It is caused by contagion from another eye, being transferred by means of the secretion.

Treatment "consists in an attempt to reduce the inflammatory symptoms and secretion, and to check and remove hypertrophy of the conjunctiva, thus shortening the duration and diminishing the liability to conjunctival cicatrization and to sequelæ. This is accomplished either by the use of certain irritating applications, or by mechanical (surgical) means.

Irritating Applications.—Sulphate of copper in the form of a crystal or pencil is the favorite local application. Nitrate of silver (one or two per cent. solution), glycerole of tannin (five to twenty-five per cent.), and the alum stick are also employed.

Mechanical (Surgical) Treatment includes expression, grattage, excision, curetting, electrolysis, *x*-rays, and galvano-cautery." (May's *Diseases of the Eye.*)

HISTOLOGY, BACTERIOLOGY, AND PATHOLOGY.

3. (*a*) The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

The smegma bacillus and the bacillus of leprosy behave similarly to the stain.

(*b*) The cultural and microscopical points of difference between the *Bacillus coli communis* and the *Bacillus typhosus* (of Eberth) are:

"(1) The motility of the colon bacillus is, as a rule, not very pronounced, sometimes absent; that of the typhoid bacillus is usually very active.

"(2) On gelatine plates the colon bacillus develops more rapidly and luxuriantly than the typhoid bacillus, and on potato it grows more abundantly, being almost always visible.

"(3) The colon bacillus coagulates milk with acid reaction within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk.
